This book is a collective effort involving hundreds of technical specialists. It brings together a wealth of information from worldwide sources to help scientists, engineers, and technicians solve current and long-range problems.

Great care is taken in the compilation and production of this Volume, but it should be made clear that NO WARRANTIES, EXPRESS OR IMPLIED, INCLUDING, WITHOUT LIMITATION, WARRANTIES OF MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE, ARE GIVEN IN CONNECTION WITH THIS PUBLICATION. Although this information is believed to be accurate by ASM, ASM cannot guarantee that favorable results will be obtained from the use of this publication alone. This publication is intended for use by persons having technical skill, at their sole discretion and risk. Since the conditions of product or material use are outside of ASM's control, ASM assumes no liability or obligation in connection with any use of this information. No claim of any kind, whether as to products or information in this publication, and whether or not based on negligence, shall be greater in amount than the purchase price of this product or publication in respect of which damages are claimed. THE REMEDY HEREBY PROVIDED SHALL BE THE EXCLUSIVE AND SOLE REMEDY OF BUYER, AND IN NO EVENT SHALL EITHER PARTY BE LIABLE FOR SPECIAL, INDIRECT OR CONSEQUENTIAL DAMAGES WHETHER OR NOT CAUSED BY OR RESULTING FROM THE NEGLIGENCE OF SUCH PARTY. As with any material, evaluation of the material under end-use conditions prior to specification is essential. Therefore, specific testing under actual conditions is recommended.

Nothing contained in this book shall be construed as a grant of any right of manufacture, sale, use, or reproduction, in connection with any method, process, apparatus, product, composition, or system, whether or not covered by letters patent, copyright, or trademark, and nothing contained in this book shall be construed as a defense against any alleged infringement of letters patent, copyright, or trademark, or as a defense against liability for such infringement.

Comments, criticisms, and suggestions are invited, and should be forwarded to ASM International.

Foreword

This work, *Corrosion: Environments and Industries*, is application driven. The best practices in segments of industry with respect to materials selection, protection of materials, and monitoring of corrosion are presented. The challenges of local environments encountered within these industries, as well as large-scale environmental challenges, are documented. The choice of solutions to these challenges can be found.

Just as the environment affects materials, so also corrosion and its by-products affect the immediate environment. Nowhere is the immediate effect of more concern than in biomedical implants. We are pleased with the new information shared by experts in this field.

As we recognize the energy costs of producing new materials of construction, the creation of engineered systems that will resist corrosion takes on added importance. The importance and costs of maintenance have been discussed for many of the industrial segments—aviation, automotive, oil and gas pipeline, chemical, and pulp and paper industries, as well as the military. The consequences of material degradation are addressed as the service temperatures of materials are pushed higher for greater efficiency in energy conversion. As engineered systems are made more complex and the controlling electronics are made smaller, the tolerance for any corrosion is lessened.

ASM International is deeply indebted to the Editors, Stephen D. Cramer and Bernard S. Covino, Jr., who envisioned the revision of the landmark 1987 *Metals Handbook*, 9th edition, Volume 13. The energy they sustained throughout this project and the care they gave to every article has been huge. The resulting three Volumes contain 281 articles, nearly 3000 pages, 3000 figures, and 1500 tables—certainly impressive statistics. Our Society is as impressed and equally grateful for the way in which they recruited and encouraged a community of corrosion experts from around the world and from many professional organizations to volunteer their time and ability.

We are grateful to the 200 authors and reviewers who shared their knowledge of corrosion and materials for the good of this Volume. They are listed on the next several pages. And again, thanks to the contributors to the preceding two Volumes and the original 9th edition *Corrosion* Volume.

Thanks also go to the members of the ASM Handbook Committee for their involvement in this project and their commitment to keep the information of the *ASM Handbook* series current and relevant to the needs of our members and the technical community. Finally, thanks to the ASM editorial and production staff for the overall result.

Preface

Corrosion, while silent and often subtle, is probably the most significant cause of physical deterioration and degradation in man-made structures. The 2004 global direct cost of corrosion, representing costs experienced by owners and operators of manufactured equipment and systems, was estimated to be \$990 billion United States dollars (USD) annually, or 2.0% of the \$50 trillion (USD) world gross domestic product (GDP) (Ref 1). The 2004 global indirect cost of corrosion, representing costs assumed by the end user and the overall economy, was estimated to be \$940 billion (USD) annually (Ref 1). On this basis, the total cost of corrosion to the global economy in 2004 was estimated to be approximately \$1.9 trillion (USD) annually, or 3.8% of the world GDP. The largest contribution to this cost comes from the United States at 31%. The next largest contributions were Japan, 6%; Russia, 6%; and Germany, 5%.

ASM Handbook Volume 13C, Corrosion: Environments and Industries is the third and final volume of the three-volume update, revision, and expansion of *Metals Handbook*, 9th edition, Volume 13, *Corrosion*, published in 1987. The first volume—Volume 13A, *Corrosion: Fundamentals, Testing, and Protection*—was published in 2003. The second volume—Volume 13B, *Corrosion: Materials*—was published in 2005. These three volumes together present the current state of corrosion knowledge, the efforts to mitigate corrosion's effects on society's structures and economies, and a perspective on future trends in corrosion prevention and mitigation. Metals remain the primary focus of the Handbook. However, nonmetallic materials occupy a more prominent position, reflecting their wide and effective use to solve problems of corrosion and their frequent use with metals in complex engineering systems. Wet (or aqueous) corrosion remains the primary environmental focus, but dry (or gaseous) corrosion is also addressed, reflecting the increased use of elevated- or high-temperature operations in engineering systems, particularly energy-related systems, where corrosion and oxidation are important considerations.

Volume 13C recognizes, as did Volumes 13A and 13B, the diverse range of materials, environments, and industries affected by corrosion, the global reach of corrosion practice, and the levels of technical activity and cooperation required to produce cost-effective, safe, and environmentally-sound solutions to materials problems. As we worked on this project, we marveled at the spread of corrosion technology into the many and diverse areas of engineering, industry, and human activity. It attests to the effectiveness of the pioneers of corrosion research and education, and of the organizations they helped to create, in communicating the principles and experience of corrosion to an ever-widening audience. Over 50% of the articles in Volume 13C are new. Looking back over the three volumes, 45% of the articles are new to the revised Handbook, reflecting changes occurring in the field of corrosion over the intervening 20 years. Authors from 14 countries contributed articles to the three Handbook volumes.

Volume 13C is organized into two major Sections addressing the performance of materials in specific classes of environments and their performance in the environments created by specific industries. These Sections recognize that materials respond to the laws of chemistry and physics and that, within the constraints of design and operating conditions, corrosion can be minimized to provide economic, environmental, and safety benefits.

The first Section is "Corrosion in Specific Environments," addressing distinct classes of environments where knowledge of the general attributes of the environment provides a "generic" framework for understanding and solving corrosion problems. By the nature of this approach, solutions to problems of corrosion performance and corrosion protection are viewed as spanning industries. The specific environments addressed in Volume 13C are fresh water, marine (both atmospheric and aqueous), underground, and military, with an eclectic mix of other environments included under specialized environments.

The second Section is "Corrosion in Specific Industries," addressing corrosion performance and corrosion protection in distinct environments created by specific industries. The specific industries addressed in Volume 13C are nuclear power, fossil energy and alternative fuels, petroleum and petrochemical, land transportation, commercial aviation, microelectronics, chemical processing, pulp and paper, food and beverage, pharmaceutical and medical technology, building, and mining and mineral processing. Corrosion issues in the energy sector receive considerable attention in this Section. In addition, there is substantial overlap between this Section and topics addressed in military environments in the first Section.

Supporting material is provided at the back of the Handbook. A "Corrosion Rate Conversion" includes conversions in both nomograph and tabular form. The "Metric Conversion Guide" gives conversion factors for common units and includes SI prefixes. "Abbreviations and Symbols" provides a key to common acronyms, abbreviations, and symbols used in the Handbook.

Many individuals contributed to Volume 13C. In particular, we wish to recognize the efforts of the following individuals who provided leadership in organizing subsections of the Handbook (listed in alphabetical order):

Chairperson	Subsection title
Alain A. Adjorlolo	Corrosion in Commercial Aviation
Vinod S. Agarwala	Corrosion in Military Environments
Hira Ahluwalia	Corrosion in the Chemical Processing Industry
Denise A. Aylor	Corrosion in Marine Environments
Bernard S. Covino, Jr.	Corrosion in Specialized Environments
Stephen D. Cramer	Corrosion in Fresh Water Environments
	Corrosion in Specialized Environments
	Corrosion in the Pharmaceutical and Medical Technology Industries
Harry Dykstra	Corrosion in the Pulp and Paper Industry
Dawn Eden	Corrosion in the Petroleum and Petrochemical Industry
Barry Gordon	Corrosion in the Nuclear Power Industry
Donald L. Jordan	Corrosion in the Land Transportation Industries
Russell Kane	Corrosion in the Petroleum and Petrochemical Industry
Brajendra Mishra	Corrosion in the Mining and Metal Processing Industries
Bert Moniz	Corrosion in the Food and Beverage Industry
Seshu Pabbisetty	Corrosion in the Microelectronics Industries
Kevin T. Parker	Corrosion in Underground Environments
Larry Paul	Corrosion in the Fossil and Alternative Fuel Industries
Robert L. Ruedisueli	Corrosion in Marine Environments
John E. Slater	Corrosion in the Building Industry

These knowledgeable and dedicated individuals generously devoted considerable time to the preparation of the Handbook. They were joined in this effort by more than 200 authors who contributed their expertise and creativity in a collaboration to write and revise the articles in the Handbook, and

by the many reviewers of their articles. These volunteers built on the contributions of earlier Handbook authors and reviewers who provided the solid foundation on which the present Handbook rests.

For articles revised from the 1987 edition, the contribution of the previous author is acknowledged at the end of the article. This location in no way diminishes their contribution or our gratitude. Authors responsible for the current revision are named after the title. The variation in the amount of revision is broad. The many completely new articles presented no challenge for attribution, but assigning fair credit for revised articles was more problematic. The choice of presenting authors' names without comment or with the qualifier "Revised by" is solely the responsibility of the ASM staff.

We thank ASM International and the ASM staff for their skilled support and valued expertise in the production of this Handbook. In particular, we thank Charles Moosbrugger, Gayle Anton, Diane Grubbs, and Scott Henry for their encouragement, tactful diplomacy, and many helpful discussions. We are most grateful to the National Energy Technology Laboratory (formerly the Albany Research Center), U.S. Department of Energy, for the support and flexibility in our assignments that enabled us to participate in

this project. We especially thank our supervisors, Jeffrey A. Hawk and Cynthia A. Powell, for their gracious and generous encouragement throughout the project.

Introduction to Corrosion in Specific Environments

Stephen D. Cramer, National Energy Technology Laboratory, U.S. Department of Energy

ENVIRONMENT is an explicit element of all corrosion processes. It is the sum of all those factors external to the corroding metal or alloy (and associated corrosion films) that affect the corrosion process. It includes the fluids that render charge transfer reactions possible. It makes possible the delivery of reactants to corrosion sites and the removal of products of corrosion reactions. It provides the medium through which transport of ionic species between anodic and cathodic sites occurs. It connects the atomic- and molecular-level processes of corrosion with the macroscopic processes of chemical processing, construction, energy production, electronics, food processing, manufacturing, medical technology, mining, and transportation. In doing so, it engages chemical, biochemical, and mechanical processes in affecting the corrosion process.

Complex technological processes often involve many and varied environments that affect corrosion performance, corrosion protection, and corrosion control. While these environments may share similarities with others when organized by unit operation or process, they are typically treated on the basis of the industry, specifically its needs and conditions. However, there are environments where the knowledge required to solve corrosion problems spans industries, and corrosion practices translate from one industry to another with regard to these environments. These are the subject of this section and include: freshwater environments, marine environments, and underground environments. Military environments are included here as well, as military weapons systems and technology must be capable of operating at the extremes of the physical world. Specialized environments are also included, representing less-well-known environments with more limited applications, but with important impacts on human activities.

Corrosion in Freshwater Environments

This environment is characterized by waters that generally come from precipitation, are not

salty, contain minimal quantities of dissolved solids, especially sodium chloride, and is usually defined as containing less than 1000 mg dissolved solids per liter (mg/L) (equivalent to 1000 ppm). Water containing 500 mg/L (ppm) or more of dissolved solids is generally undesirable for drinking and many industrial uses. *Potable water and building water* systems are characterized by waters containing low levels of dissolved solids, some chemicals added for public health reasons, and low residence times in the distribution system. Ductile iron (usually lined inside) is favored for water mains, while copper is the choice for bringing water from the main to the customer. However, use of plastic in lieu of copper is increasing. *Ultrapure water* systems are needed in laboratories and high-technology manufacturing processes. *Service water* systems are auxiliary water systems typically using “raw” or untreated water for cooling in fossil-fuel and nuclear power plants. The primary corrosion challenges are related to the chemistry of the “raw” water, stagnant conditions, flow variations, and temperature variations. *Wastewater* can contain substantial levels of dissolved solids (including chlorides and sulfates), suspended solids, and biomaterials. Biochemical oxygen demand (BOD), chemical oxygen demand (COD), pH, Langelier index (related to scale formation and corrosion), and sulfide generation are important considerations in selecting materials for service in wastewater and atmospheric service in wastewater treatment plants.

Corrosion in Marine Environments

Such conditions occur in seawater and atmospheric environments associated with the world’s oceans. Seawaters are salty, containing substantial quantities of dissolved solids, especially the chloride and sulfate salts of sodium, magnesium, calcium, and potassium. In more than 97% of the seawater, the concentration of dissolved solids is between 33,000 and 37,000 mg/L (ppm). Microorganisms and dissolved gases are other important constituents of

seawater. Brackish waters, found at the margins of seawater and freshwater, have dissolved solids concentrations between 1000 and 35,000 mg/L (ppm). *Seawater* corrosion exposures include full-strength open ocean water, coastal seawater, brackish and estuarine waters, and bottom sediments. Seawater is a biologically active medium and biofouling contributes to the complexity of corrosion processes in seawater, particularly to the occurrence of localized corrosion processes. Corrosion in *marine atmospheres* is distinguished by the presence of airborne contaminants, particularly chlorides, by the availability of moisture in fogs, dew, and precipitation, and by the distance from the sea. Nickel alloys and stainless steels have good corrosion resistance in marine atmospheres.

Sacrificial *metallic coatings* applied by thermal spray, hot dipping, or electroplating can add up to 20 years service life to steel structures in marine atmospheres. Aluminum and zinc coatings are the primary coatings in use and thickness, composition, and microstructure of the coating are the key variables affecting service life of the coated structure. *Organic coatings* are the principal means of corrosion control for ship hulls and topsides and for the splash zones on offshore structure and can be used with sacrificial metallic coatings to extend service life. Corrosion protection of marine pipelines is usually achieved through the use of protective coatings and supplemented by using *cathodic protection*. Sacrificial anodes are often chosen for offshore platforms because they are simple, rugged, and become effective immediately on platform launch. The primary corrosion protection for ship hulls is provided by coatings, augmented by cathodic protection to protect areas of coatings holidays and damage.

Corrosion in Underground Environments

Detection of corrosion in underground environments relies on a variety of electrochemical inspection and monitoring techniques for determining the condition of structures in or on the ground and, in many cases, unavailable for visual

inspection. *External corrosion direct assessment* (ECDA) is a structured process intended for use to assess and manage the impact of external corrosion on the integrity of underground pipelines. It integrates field measurements with the physical characteristics, environmental factors, and operating history of pipelines. It includes nonintrusive, aboveground examinations with pipeline physical examinations (direct assessment) at sites identified by assessment of the indirect examinations. *Close interval survey* techniques involve a series of structure-to-electrolyte potential measurements on a buried or submerged structure, most often a pipeline. Close interval surveys are used to assess the performance and operation of cathodic protection systems. Additional benefits include identifying areas of inadequate CP or excessive polarization, locating medium-to-large defects in coatings on existing or newly constructed pipelines, locating areas of stray-current pickup and discharge, identifying possible shorted casings and defective electrical isolation devices, locating possible high-pH stress-corrosion cracking risk areas, and locating areas at risk of external corrosion.

Storage tanks are designed to store products economically and in an environmentally safe way. Internal corrosion can be controlled by a combination of protective coatings and cathodic protection. Soil-side external corrosion can be mitigated by cathodic protection with and without the use of protective coatings. Aboveground steel storage tanks are designed to last for 20 to 30 years.

Well casing corrosion above depths of 60 m (200 ft) is typically due to oxygen reduction enhanced by chlorides and sulfates, while below this depth corrosion is caused by carbon-dioxide-rich formation water. Cathodic protection of well casings has proven to be an effective means of minimizing corrosion on the casing provided the proper amount of current is applied and maintained. Isolating the casing from surface facilities eliminates the macro corrosion cell between the casing and these structures and provides a means for controlling and measuring the protection current to the casing.

Direct Current (dc) stray currents accelerate the corrosion of structures where a positive current leaves the structure to enter the earth or an electrolyte. Stray currents also corrupt potential measurements that are being taken to establish a cathodic protection criterion. Stray currents (direct and alternating) can be controlled by alteration of the source, addition or adjustment of cathodic protection, and use of reverse current switches and of mitigation bonds. *Corrosion rate probes* for soil environments can employ both electrochemical and nonelectrochemical techniques for corrosion measurement. Corrosion rate probes allow continuous measurement of external corrosion rates as a function of time, as well as a way to monitor changes in soil corrosivity with time. *Pipe-type power transmission cables* provide power in cities at voltage levels that can be used by both industrial and residential

customers. Cathodic protection is necessary to prevent corrosion damage that would allow the loss of pressurized dielectric fluid from the pipe. The dc potential of the pipe must be more negative (approximately -0.5 V) than the earth around it. All acceptable CP systems for doing this must be capable of safely conducting high alternating current (ac) fault currents to ground.

Corrosion in Military Environments

Corrosion is a major concern of the U.S. Department of Defense (DoD) and is estimated to cost at least \$20 billion (U.S.) annually. This concern is reflected in the DoD Corrosion Policy initiated in 2003 (Ref 1) providing guidance to procurement personnel, maintenance units, and service personnel who must see that limited resources are efficiently used and that the readiness of the military is not compromised by materials failures. Military assets include more than 350,000 ground and tactical vehicles, 15,000 aircraft, 1000 strategic missiles, 300 ships, and facilities worth roughly \$435 billion (U.S.). Since the military does not choose where its next battle must be fought, military assets must perform reliably and effectively at the extremes of the physical world. Embedded in these extremes is damage due to corrosion, wear, and the synergistic effects of corrosion and wear. The primary means for ensuring that raw materials, commodities, materials of construction, and manufactured equipment and systems meet the needs of the military services is the DoD system of *military specifications and standards*. These are supplemented by the standards and practices of NACE International, ASM International, and ASTM International, and other professional organizations.

Corrosion problems associated with *military facilities* and installations are similar to those encountered at civilian facilities. They represent some of the most costly and pervasive maintenance and repair problems in the services. *High-temperature corrosion and oxidation* of metals and alloys occurs in many military applications, including power plants (coal, oil, natural gas, and nuclear), land-based gas turbine and diesel engines, gas turbine engines for aircraft, marine gas turbine engines for shipboard use, waste incineration, high-temperature fuel cells, and missile components. Predicting corrosion performance in these applications is difficult because of the variety of materials used, the operational demands placed on the materials, and because the materials often degrade by more than one mechanism. *Armament corrosion* protection relies heavily on coatings systems and regular maintenance to prevent damage, not only in service, but during the extended periods of storage common to these systems. The Army has one of the largest *ground vehicle fleets* in the world, having an average vehicle age of more than 17 years (well past the manufacture's corrosion warranty for commercial vehicles), and

relies on accelerated corrosion testing to identify improved materials, coatings systems, corrosion inhibitors, design, and maintenance practice to ensure continued satisfactory long-term vehicle performance.

Military coatings systems typically have multifunctional performance requirements, ranging from corrosion protection, oxidation resistance, wear resistance, camouflage, spectral reflectance, adhesion, weatherability, and mar resistance. The chemical agent resistant coating (CARC) systems, in use since 1983, provide a wide selection of coatings for corrosion protection in military environments. Traditional coatings for *military aircraft* include inorganic pretreatments, epoxy primers, and polyurethane topcoats. Chromate continues to be eliminated from aluminum aircraft pretreatments and from sealers for anodized aluminum; low- and no-VOC (volatile organic coating) polymer binder systems are increasingly being used on military aircraft.

Navy aircraft experience severe corrosion conditions in operational service. Life-cycle costs are high due to increased maintenance and decreased component/system reliability as a result of cumulative corrosion damage. Cleaning, washing, inspection, surface treatments, and coatings form the core of navy aircraft maintenance. Historical data show that *fatigue and corrosion* cause 55 and 25% of aircraft failures, respectively, while corrosion contributes to only a small fraction of the fatigue failures. However, corrosion damage can result in an initial flaw that dramatically reduces the predicted fatigue life of critical components and renders noncritical components as critical.

The corrosion of *electronic equipment* is most greatly affected by: temperature, moisture, biological growth, rain, salt spray, dusts, shock, and vibration. The Navy found that 40 to 50% of corrosion-damaged printed circuit boards could be returned to service by simply cleaning corrosion products from the contacts. More than 90% of failed removable electronic assemblies could be returned to weapons service when repaired by trained technicians following recommended practices.

Microorganisms, including both bacteria and fungi, can accelerate corrosion reactions and change reaction mechanisms in atmospheric, hydrocarbon/water, immersed, and burial environments encountered in military operations. The main consequence of biofilm formation on cathodically protected carbon steel is to increase the current density necessary to polarize the steel to the protected potential. Shrinking military budgets and escalating weapons systems costs have led to increasing efforts to extend the *service life* of aging military equipment (characterized by decreasing structural strength and increasing maintenance costs). Effective life-cycle cost modeling combines traditional operational and support cost elements with an expert analysis system and demonstrates built-in flexibility and ease of updating with new information.

Corrosion in Specialized Environments

Specialized environments address an eclectic mix of environments that are important to human activities. Water is supercritical above its vapor-liquid critical point, 374 °C (706 °F) and 22 MPa (3.191 ksi). Supercritical water has unique solvating, transport, and compressibility properties compared to liquid water and steam. These properties are finding growing commercial applications. Two of these addressed here are waste destruction using *supercritical water* and the use of *ultrasupercritical water* (temperatures above 565 °C, or 1050 °F) for power production.

Corrosion in *cold climates* challenges the conditions typically addressed in atmospheric corrosion. Solar heating can produce water at ambient temperatures below the freezing point; melt water can concentrate corrosive ions; extreme climatic conditions make maintenance and repairs difficult. These factors place unexpected corrosion demands on structures expected

to serve with little or no maintenance for very long times.

Emission-control equipment operates in an environment that brings together acidic gases, particulates, water vapor (and condensed water), and large volumes of exhaust gas. Design and materials selection are crucial factors in mitigating corrosion damage under such conditions.

Corrosion of *recreational equipment* has little visibility to the consuming public through efforts by the wide and diverse recreational equipment community to produce products that are safe and meet public expectations for performance and service. Corrosion is discussed as it relates to four consumer products: recreational boats, firearms, playground equipment, and bicycles. *Workboats, traditional, and recreational boats* function in one of the more corrosive environments commonly encountered. Materials selection, galvanic corrosion, cathodic protection, and design are critical elements in reducing the impact of corrosion on boat service life, performance, and safety.

Cultural resources and artifacts are aesthetically and historically important objects that people choose to preserve for the present and future generations. The significant challenges to doing so are discussed in three papers addressing *museum environments, outdoor environments*, and the recovery of artifacts from *buried environments*.

Process equipment may need to be chemically cleaned to operate properly, efficiently, and according to specifications. Such cleaning should be addressed during the equipment design to minimize the effects of corrosion on materials damage and service life.

Corrosion in Potable Water Distribution and Building Systems

Windsor Sung, Massachusetts Water Resources Authority

WATER IS ESSENTIAL TO LIFE. It is no exaggeration to say that civilizations rose and fell with their ability to procure and convey water of good quality to their citizens. Construction of the needed conveyances tends to be resource extensive, so the chosen construction materials need to last. Early favored materials were wood, stone, and brick. Now materials selected include metals, cement, and plastics. As metals are strong, durable, and ductile, they have been the material of choice in modern times. Iron has been most extensively used of the metals that are used for water distribution. Others include aluminum, copper, and lead. The iron is in the form of pig iron, cast iron, steel, ductile iron, or galvanized iron. Modern water utilities favor the use of ductile iron (usually lined internally) for water mains. The metal of choice for bringing water from the main to the consumer tends to be copper. The use of plastic in lieu of copper has grown on the consumer end, albeit slowly.

Table 1 summarizes the water quality effects from interaction of water with different materials that are commonly used in water distribution pipes (Ref 1). This article focuses on the internal corrosion of iron and copper in potable water as these are still the prevalent materials. External corrosion of pipes is a serious problem that is addressed in the articles "Stray Currents in Underground Corrosion" and "Corrosion Rate Probes for Soil Environments" in this Volume.

While the deterioration of water quality from a public health perspective is of primary concern, there are other issues to consider. Corrosion of iron pipes tends to form deposits that over time may decrease the capacity of transmitting water, increase the pressure drop, and thus increase pumping costs. The deposits may provide safe harbor for micro-organisms, including pathogenic ones from disinfectants in the water. Sudden changes in flow velocity and/or pressure (as when fire hydrants are opened) may dislodge deposits, causing customer complaints over discolored water. Some chemicals added for mitigating water corrosion may cause scaling in heat exchangers, and some of these chemicals can be toxic to human or ecological health. These are

some of the reasons why one needs to understand and mitigate corrosion in potable water and building systems.

Theoretical Considerations

Electrochemical reactions are almost always the cause of corrosion of metals in contact with water. Metals in their elemental state are unstable in the presence of water and dissolved oxygen. For corrosion to occur, all the components of an electrochemical cell are needed: an anode, a cathode, and an electrolyte to complete

the circuit. The electrochemical reactions are sometimes called reduction-oxidation (redox) reactions. Thermodynamics and equilibrium concepts are useful for understanding the phenomena.

At the anode, the metal loses electrons and is oxidized. The cathode is where the electron is gained and the electron gainer (or acceptor) can be dissolved oxygen, which is then reduced. It is not clear what factors influence the distribution of anodic and cathodic areas on the surfaces of pipes. The Nernst equation is commonly used to describe redox reactions theoretically, but its practical use is limited. See the articles

Table 1 Corrosion and water-quality problems caused by materials in contact with drinking water

Material	Corrosion type	Tap water quality deterioration
Cement-based		
Asbestos cement(a)	Uniform corrosion	Calcium dissolution. Increased pH values (up to 12). For asbestos-cement pipes, in unstable waters, pH increases and asbestos fibers can be found in the water. Surface roughening, strength reduction, and pipe failure. Aluminum release
Concrete		
Cement mortar(b)		
Iron		
Cast	Uniform corrosion	Rust tubercles leading to blockage of pipe
Ductile	Graphitization	Iron and suspended particles release
	Pitting under unprotective scale	
Steel	Pitting	Rust tubercles (blockage of pipe). Iron and suspended particles release
Galvanized steel	General pitting corrosion	Excessive zinc, lead, cadmium, iron release, and blockage of pipe
Copper		
	Uniform corrosion	Copper release
	Localized attack	Pipe perforation and subsequent leakage from pipes
	Cold-water pitting (type I)	
	Hot-water pitting (type II)	
	Other types of localized attack	
	Microbiologically influenced corrosion	Leakage from pipes and sporadic blue deposit release. Rupture of pipes and fittings and consequently leakage
	Corrosion fatigue	
	Erosion corrosion	Leakage from pipes
Brass	Erosion and impingement attack	Penetration failures of piping
	Dezincification	Blockage of pipes and fittings
	Stress corrosion	Lead and zinc release
Lead		
Lead pipe	Uniform corrosion	Lead release
Lead-tin solder	Uniform corrosion	Lead and cadmium release
Plastic	Possible degrading by sunlight and microorganisms	Taste and odor

“Electrode Potentials” and “Potential versus pH (Pourbaix) Diagrams” in Volume 13A, *ASM Handbook*, 2003. One of the useful associated parameters from the Nernst equation is the standard electrode potential for classification purposes. The galvanic series is a compilation of standard electrode potentials. Older literature lists the galvanic series as anodic (oxidation) reactions, for example, $\text{Zn(s)} = \text{Zn}^{2+} + 2e^-$. Metals with high positive potentials (in this case the standard potential is +0.76 V) are more readily oxidized in this convention. The preferred convention today is to write cathodic (reduction) reactions, $\text{Zn}^{2+} + 2e^- = \text{Zn(s)}$. The standard potential referenced to the standard hydrogen potential (SHE) in this case is -0.76 V, and metals with large negative potentials are more readily oxidized. This is an unfortunate point of confusion, but cannot be avoided since conventions do change with time. A partial galvanic series of metals relevant to water distribution is shown in Table 2. More easily corroded metals are on top, and the bottom ones are mostly inert and are sometimes referred to as noble metals. This series shows how galvanic protection works, which is the use of a more readily corroded metal such as zinc as a sacrifi-

cial anode in order to protect material such as iron pipe. It also explains galvanic corrosion, which occurs when two dissimilar metals are in contact with each other and electrons flow preferentially from one to the other.

The reduction of oxygen in water produces hydrogen ions, which impacts pH. In addition, ferrous iron is unstable with respect to ferric iron in the presence of oxygen. Therefore, the corrosion of iron is accompanied by pH changes and formation of iron oxide and oxyhydroxides. These reactions are most conveniently summarized by E_H -pH diagrams, also known as Pourbaix diagrams. The redox potential of a half reaction (written as a reduction reaction) in reference to the SHE is the definition for E_H . Just as pH is defined as $-\log\{\text{H}^+\}$ where $\{\text{H}^+\}$ is the activity of the aqueous proton, p_e is defined as $-\log\{e^-\}$ where $\{e^-\}$ is the activity of the free aqueous electrons and is related to E_H . Figure 1 (Ref 2) shows such a diagram for ferric hydroxide with ionic activities of dissolved species set to be 1 μmol . As such, it is a graphical summary of thermodynamic information. Exact locations of the lines depend on the free energy of formation of the species and phases in question. The stability field of water is outlined by the two diagonal lines (identified by regions O_2 H_2O , H_2 H_2O), although in practice it would be rare for potable water to have a pH of less than 6 and greater than 10. The diagram shows that the stable phase for iron under mildly oxidizing

environments and typical pH values is ferric hydroxide.

Figure 2 shows a 1.5 m (60 in.) cast iron water main that has been in contact with water. Mushroomlike ferric tubercles have formed on its interior surface. Detailed analyses of similar deposits have shown the presence of ferrous solids such as ferrous carbonate (siderite), mixed ferrous-ferric solids (green rust, magnetite), various ferric oxyhydroxides (goethite, lepidocrocite), and amorphous ferric hydroxide. In principle, each distinct solid would have different energies of formation and occupy different regions in the E -pH diagram. Increasing levels of chloride and sulfate enhance corrosion by increasing conductance of the electrolyte. Their presence appears to be important for the formation of green rust. Micro-organisms also play an important role in enhancing corrosion of iron water mains.

Copper plumbing tube has been standard for water distribution in buildings in the United States for the last half century. It has a relatively high standard reduction potential and the corrosion mechanisms are very different from that of iron. Pitting corrosion is an increasing problem with copper pipes leading to pinhole leaks. NACE International organized a symposium on the topic (Ref 3) and concluded that the process is not well understood. There is some evidence pointing to poor workmanship, in particular the overuse of flux as related to the development

Table 2 Partial galvanic series of metals relevant to potable water systems

Anode	Reaction	Standard reduction potential (SHE) at 25 °C (77 °F), V
Aluminum	$\text{Al}^{3+} + 3e^- = \text{Al(s)}$	-1.68
Zinc	$\text{Zn}^{2+} + 2e^- = \text{Zn(s)}$	-0.76
Iron	$\text{Fe}^{2+} + 2e^- = \text{Fe(s)}$	-0.44
Nickel	$\text{Ni}^{2+} + 2e^- = \text{Ni(s)}$	-0.25
Tin	$\text{Sn}^{2+} + 2e^- = \text{Sn(s)}$	-0.14
Lead	$\text{Pb}^{2+} + 2e^- = \text{Pb(s)}$	-0.13
Copper	$\text{Cu}^{2+} + 2e^- = \text{Cu(s)}$	+0.34
Gold	$\text{Au}^{2+} + 2e^- = \text{Au(s)}$	+1.50

Fig. 1 E -pH diagram for iron-water system at 25 °C (77 °F). It is a graphic representation of thermodynamic stability. The potential E_H is expressed in reference to the standard hydrogen potential. p_e is defined as $-\log a_{e^-}$ where a_{e^-} is the activity of the free aqueous electrons and is related to E_H .

Fig. 2 A 1.5 m (60 in.) cast iron pipe with tuberculation. Courtesy of Terry Bickford

of pits. There is also some indication that chlorination and chloramination may also impact copper corrosion. Chloramination involves the use of ammonia to bind free chlorine, and ammonia is known to complex copper effectively. Copper oxide/hydroxide solubility exhibits the classic U-shaped curve with respect to pH. Increasing pH beyond 9 promotes the formation of copper hydroxide complexes and increases copper solubility.

The traditional way that water chemists deal with corrosion control of potable water systems is to calculate indices such as the Langelier saturation index (LSI). See the articles "Modeling Corrosion Processes" and "Corrosion Inhibitors in the Water Treatment Industry" in Volume 13A, *ASM Handbook*, 2003. The LSI measures the degree of saturation of the water with respect to calcium carbonate scale. Corrosive water has a negative LSI, which means it will tend to dissolve calcium carbonate scale. Noncorrosive water has a positive LSI, which means it has a tendency to form calcium carbonate scale. In this sense, noncorrosive water may not be a good thing, since calcium carbonate scale is less soluble with rising temperatures. Water with a positive LSI will have a tendency to form scales in hot water heaters. However, scaling can be a problem in cold water, too. The LSI calculation is not complicated and references such as Ref 2 can be consulted. Inputs include the amount of calcium, pH, and alkalinity, as well as the total dissolved solids (TDS). However, the LSI is not very useful for determining other corrosion issues.

The LSI applies solubility reactions, which are described by solubility product, written as K_{sp} . K_{sp} of calcium carbonate is written as the product $\{Ca^{2+}\} \times \{CO_3^{2-}\}$ and has the numerical value of 5×10^{-9} (M^2) at 25 °C (77 °F) (Ref 4). $\{Ca^{2+}\}$ is the activity or ideal concentration of calcium ions, and $\{CO_3^{2-}\}$ is the carbonate ion activity. Equilibrium constants are functions of temperature. The activity is related to actual concentration modified by an activity coefficient (function of ionic strength, which is related to total dissolved solids). If the ion activity product (IAP) of the calcium multiplied by the carbonate ion (related to alkalinity and pH) exceeds the solubility product, the solution is supersaturated and there is a tendency for scale to form (i.e., the solution has a positive LSI). The solution has a negative LSI if the IAP is less than the solubility product or there is a tendency for preformed calcium carbonate scale to dissolve. Ideally, the LSI should be close to 0. Figure 3 gives an alternate way of showing basically same idea as a LSI calculation. It depicts the amount of calcium that would be in equilibrium with the given pH at two alkalinity values (5 and 30 mg/L as calcium carbonate). It is calculated for a temperature of 25 °C (77 °F) and does not include activity corrections (the TDS term). Decreases in temperature and increases in TDS will increase the equilibrium calcium value so this figure actually shows conservative results. When alkalinity is relatively low at 5 mg/L,

calcium concentration has to be in excess of 400 mg/L to form scale at pH of 8. This water has a negative LSI and would be termed corrosive. The amount of calcium necessary to be scale forming at a pH of 9 and an alkalinity of 30 mg/L is only about 8 mg/L.

Another index found in corrosion literature is the Larson Index (LaI). The Larson index compares the ratio of the sum of sulfate and chloride to the bicarbonate ion (all expressed as equivalents per liter). Empirical observations show a Larson Index of less than 0.7 is desirable for corrosion control.

Mitigation against Corrosion

There are two major ways of mitigation against corrosion in potable water systems. The first is to line the pipe surface physically such that water and dissolved oxygen (or other electron acceptors) cannot reach the metal surface. Common lining materials include concrete, asbestos-cement, and epoxies. Concrete is alkaline and the pH of stagnant water in contact with concrete can exceed 10. The alkaline water can react with copper plumbing through hydrolysis reactions, and consumers may complain of copper staining such as green and blue water. Improperly installed or cured epoxy liners can deteriorate and leach organic compounds into water, causing taste and odor complaints.

The second method is to add chemical inhibitors to alter water chemistry to mitigate against corrosion. See the article "Corrosion Inhibitors in the Water Treatment Industry" in Volume 13A, *ASM Handbook*, 2003. In many cases the added chemical causes a scale to form on the pipe surface, so it behaves like a liner. Changing water quality to achieve a positive LSI promotes the formation of a calcium carbonate (calcite) scale to protect against corrosion. This is usually achieved by adding sodium or potassium hydroxide, calcium hydroxide, and or sodium carbonate to increase pH and alkalinity. Incidentally, increased pH and alkalinity is one of the options for lowering lead levels in potable water, and the mechanism may involve the formation of a basic lead carbonate scale. Another commonly used chemical for corrosion control is zinc orthophosphate. The common

Fig. 3 Amount of calcium in equilibrium with calcite at alkalinity values of 5 and 30 as a function of pH. This is a graphic interpretation of the Langelier saturation index.

recommendation is to dose enough chemical to achieve a zinc concentration of about 2 mg/L at a pH between 7.5 and 7.8. The K_{sp} for $Zn_3(PO_4)_2$ is about 10^{-32} (M^5) (Ref 4) and is equal to the product $\{Zn^{2+}\}^3 \times \{PO_4^{3-}\}^2$. The amount of total phosphorus is related to the amount of zinc added (if the raw water phosphate concentration is negligible). The fraction of total phosphorus that is phosphate is a function of pH and the acidity constants of phosphoric acid. Figure 4 is a plot of the theoretical amount of zinc that is in equilibrium with zinc phosphate scale (with the given solubility product), with the zinc and phosphate coming from the chemical addition alone. The agreement with the general rule of thumb to achieve zinc in the mg/L range at pH less than 8 shows that solubility calculations were used to generate the recommended doses. In some cases, far lower zinc levels are needed, and there are indications that zinc hydroxycarbonate scales are formed on cements (which may eventually convert to zinc silicates).

The use of phosphorus can include phosphoric acid as well as polyphosphates (long chain phosphate molecules), and polyphosphate/orthophosphate blends. Polyphosphates work well for sequestration of iron and manganese, but have been shown to increase lead and copper releases in soft water. Polyphosphates can also be detrimental to cement and cement linings in soft waters. When phosphates are used for corrosion control, sometimes $FePO_4$ scale may form. In other cases, the phosphate ion is adsorbed onto preexisting iron oxide scales. In fact, a whole different class of chemicals similar to phosphate is available for cooling system use, such as chromates, nitrites, and molybdates. They have been described as passivation chemicals, and the most likely reaction mechanism is their preferential adsorption onto cathodic sites, thus blocking the contact of electron acceptors such as dissolved oxygen onto the electrochemical cell. These chemicals are toxic and not used for potable water conditioning. Their discharge can sometimes pose a challenge for wastewater operations; for example, molybdenum tends to accumulate on biosolids and can exceed regulatory limits for beneficial reuse. Organic compounds such as amines can be used

Fig. 4 Calculated zinc dosage for the formation of zinc phosphate scale as a function of pH. The zinc levels shown exceed those recommended by some potable water standards.

for conditioning pipe surfaces for nonpotable use. It is assumed that the organic compound is adsorbed onto the pipe surface in thin layer coatings. Aromatic triazoles are effective corrosion inhibitors for copper and its alloys (Ref 5).

Silicates are also used for corrosion control. They can form a coating on pipes, but more likely they act like polyphosphates as sequestering agents. The exact mechanism is not fully understood, but it has been suggested that this works by adsorption again onto preexisting particulates. The surface coverage causes charge reversal and the suspension becomes stable and colloidal (less than micron size). The colloidal nature of the suspension "masks" the physical appearance of turbidity and color. Long-term use of silicates can convert carbonate and oxide scales to metal silicates.

Additional Considerations

Lead continues to be of concern even though potable water intake is not a major contributor of body burden lead. Progress has been made to replace lead pipes and goosenecks, as well as banning lead solder. However, there still remain a significant number of lead pipes that are not easily located or removed. It is now recognized that some plumbing fixtures may also contribute

lead even though they may be advertised as lead-free. It has been shown that brasses used frequently in faucets, valves, and fittings leach lead into high-purity water (Ref 6). Producing a water quality to minimize lead remains a challenging goal for every utility, and consumers are well advised to minimize lead sources within their home. There is now considerable interest in limiting the use of lead in brasses, and interest in clarifying the use of term "lead-free" in advertising plumbing products.

This discussion has relied heavily on the use of equilibrium chemistry. Corrosion concerns are driven by the kinetics of reaction and often limited by mass transfer. For example, the U.S. Environmental Protection Agency lead rule specifies collection of first-draw samples after the water has been stagnant in the pipes for 6 to 8 h. Sometimes this is an insufficient time for a system to reach equilibrium after perturbations in water chemistry.

There has been much progress made in corrosion measurements including the use of coupons, corrosion meters, rotating annular reactors with coupon inserts to study the relation between micro-organisms and corrosion rate, and polarization scans. Research involving the use of corrosion cells suitable for on-line monitoring of corrosion and metal release processes using the corrosion potential stagnation/flow (CPSF) method appear to be promising (Ref 7).

Reference 8 is suggested for a more detailed and in-depth treatment of internal corrosion and control in water systems.

Corrosion in Service Water Distribution Systems

K. Anthony Selby, Water Technology ConsultantsTM, Inc.

SERVICE WATER SYSTEMS are auxiliary cooling systems in fossil-fueled and nuclear power plants. They are separate from the steam surface condenser cooling system that condenses the main process steam for reuse in the cycle. Service water systems cool a wide range of plant components, some common to most power plants regardless of fuel type, including turbine lubricating oil coolers, generator hydrogen coolers, and pump lubricating oil coolers. Corrosion in service water systems in electric utility plants is a significant problem. This is especially true in nuclear plants because some service water systems are safety related and are required for the safe shutdown of the plant. Those systems required for a safe shutdown are labeled "safety-related," "essential," or "emergency cooling." The majority of the service water systems in nuclear plants do not fall into this category and are labeled "nonsafety-related" or "non-essential," but their unavailability may challenge continued operation of the plant.

Corrosion mechanisms in service water systems are not unique but may be exacerbated by design features and operating modes. The cost of corrosion-related failures in power plants is significant. Replacement or repair costs can be substantial because of the inaccessibility of

pipings, much of which may be underground. In addition, repairs to service water systems may necessitate plant shutdowns, the loss of production capacity, and the cost of purchasing replacement power.

In a nuclear power plant, safety-related and non-safety-related systems may use the same source of cooling water or may have separate sources. By design the safety-related service water system is a redundant and secure water source representing the ultimate heat sink for the plant.

In the United States, the Nuclear Regulatory Commission (NRC) has closely scrutinized safety-related service water systems in nuclear plants. In 1989, in response to a number of problems associated with these systems across the nuclear industry in the previous decade, the NRC issued "Generic Letter (GL) 89-13" (Ref 1). The overwhelming majority of the problems were the result of biological macrofouling, human error, or corrosion. In order to address these areas, GL 89-13 recommended that nuclear plants establish ongoing programs that would evaluate the reliability and operability of their safety-related service water systems, against the design requirements of those systems, which were specified in the laws that governed the NRC

licenses for those plants. Today, it is recognized that GL 89-13 has been successful in focusing the proper level of attention on these systems. Additionally, in view of the increasing economic importance of operating these systems past their original design lifetimes, the nuclear industry has recognized that corrosion and corrosion control are increasingly playing more significant roles in service water system reliability.

Typical System Designs

Most service water systems use raw water for cooling purposes. Raw water is defined as untreated water such as that provided by a lake or river. It can also refer to the same water used in a cooling tower. Two typical designs are shown in Fig. 1 and 2. There are numerous variations on these designs.

In Fig. 1, the raw water from a lake or river passes through the service water system and is then used as makeup to the cooling tower. The cooling tower recirculating water removes heat from the main surface condenser.

In Fig. 2, there is no cooling tower. Both the service water system and circulating water system (surface condenser cooling water) are

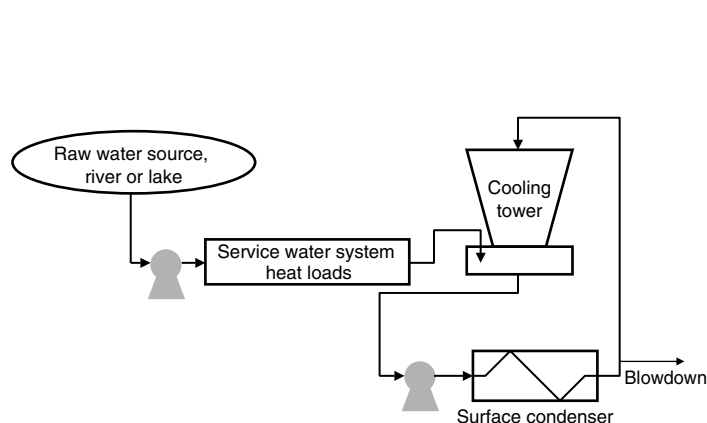

Fig. 1 Typical arrangement where raw water is used in service water system and as makeup to the cooling tower. Because the condenser loop is an open-recirculating system, make-up water is needed to replace evaporation and blowdown.

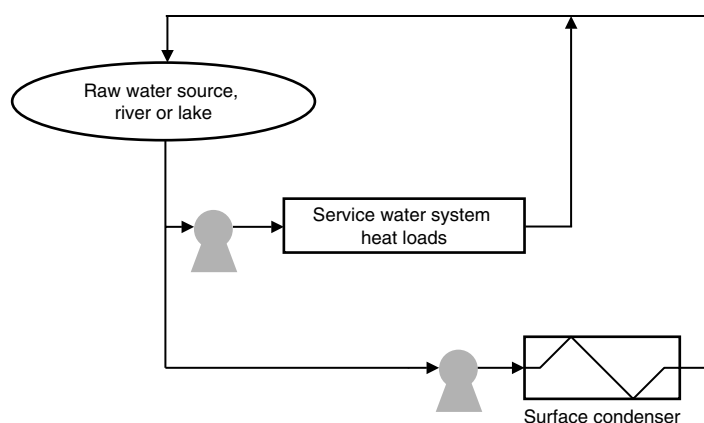

Fig. 2 In a once-through service water and circulating water system without a cooling tower large quantities of water are circulated through the systems and back to the source.

“once-through” from the lake or river and back again.

Some power plants have a service water system consisting of a closed loop of treated water that is cooled by a raw water heat exchanger (Fig. 3). This is typical of plants that utilize seawater or brackish water for cooling.

Materials of construction in service water systems vary from plant to plant. In many cases piping is constructed of unlined carbon steel. In some cases, cement lined carbon steel, lined (epoxy coated) carbon steel, stainless steels, copper alloys, or titanium are used. Stainless steels are typically 300 series austenitic grades but other alloys such as 6% molybdenum austenitic stainless steel are sometimes used.

Heat exchanger tubing is usually constructed of copper alloys (copper, copper-nickel, brasses), stainless steel, or titanium. Two of the most common copper alloys are 90-10 copper-nickel and admiralty brass. Stainless steels are typically 300 series austenitic grades but other alloys are sometimes used. These alloys can include 6% molybdenum austenitic stainless steel and high chromium-molybdenum ferritic stainless steel. Carbon steel is not used for power plant service water heat exchanger tubing.

Typical Water Qualities

The waters used in service water systems can have wide variations in constituents and impurities. Some typical values are shown in Table 1.

Corrosion Mechanisms in Service Water Systems

Corrosion mechanisms applicable to service water systems include general corrosion, concentration cell corrosion which includes crevice, tuberculation, and under-deposit corrosion (UDC), microbiologically influenced corrosion (MIC), galvanic corrosion, stress corrosion cracking (SCC), and dealloying. General corrosion rates vary greatly because some waters are much more aggressive than others. Localized forms of corrosion, pitting, concentration cell corrosion and MIC are of particular concern because of the impact on metal integrity.

General corrosion, concentration cell, and MIC are the corrosion mechanisms of greatest concern with regard to carbon steel components. Copper alloy components can suffer from pitting, dealloying, and SCC. Stainless steels in the 300 series can suffer from pitting and SCC and are also susceptible to MIC failure.

Corrosion Challenges in Service Water Systems

The primary corrosion challenges in service water systems are related to the basic characteristics of oxygen saturated raw water and the

system design. Necessary design results in climatic and temperature induced flow variations, and redundant equipment requires cross-connecting piping that undergoes stagnant or, even worse, intermittent flow conditions.

An example is a turbine lubricating oil cooler. Typically, the oil flows through the shell side of one 100% capacity heat exchanger at a constant rate. The service water flows through the heat exchanger tubes and that flow is throttled to maintain the oil temperature within a specified range. For large base-loaded fossil and nuclear plants, fully redundant heat exchangers are provided in order to maintain operational flexibility. These redundant piping systems remain stagnant when not in service, assuming that their isolation valves are leak tight. Under warm weather conditions, the service water flow control valves for the in-service heat exchanger may operate completely open. In many cases the control valves have one or more bypass lines installed for summer conditions. Under cold weather conditions, the control valves throttle flow to

maintain oil temperatures above recommended minimums. This means that flow velocities are high during warm weather and low during cold weather. Operation at low cooling water velocities and intermittent and trickle flow conditions allows for the accumulation of sediment and encourages the formation of other deposits in the piping and heat exchangers. The accumulation of sediments and deposits contributes to UDC and tuberculation through a mechanism of oxygen concentration differential cell corrosion.

Another challenge is the presence of microorganisms in the raw water that may contribute to MIC, which can cause failures in service water piping and heat exchangers. Types of bacteria related to MIC include sulfate reducing bacteria (SRB), acid-producing bacteria (APB), and iron-depositing bacteria. See the article “Microbiologically Influenced Corrosion” in Volume 13A and “Microbiologically Influenced Corrosion in Military Environments” in this Volume. Microbiological growth can also cause problems in service water systems. In fresh water systems,

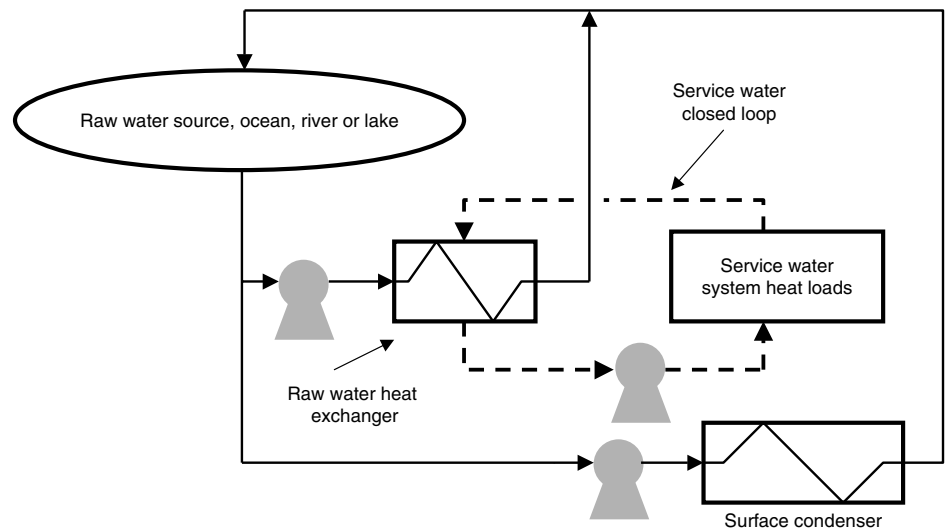

Fig. 3 A closed loop service water system typical for plants using sea water as the prime coolant. As the service loop is a closed-recirculating system, little make-up water is needed.

Table 1 Typical water quality in service water systems

Constituent	Fresh surface water	Fresh ground water	Brackish water	Saline water
Total dissolved solids, mg/L	80–1500	100–1500	1500–3000	> 3000
Conductivity, $\mu\text{S}/\text{cm}$	120–2000	150–2000	2000–4000	> 4000
Total hardness CaCO_3 , mg/L(a)	5–300	5–300	50–1000	50–2000
Calcium hardness CaCO_3 , mg/L(b)	3–200	3–200	30–800	9–30–800
Magnesium hardness CaCO_3 , mg/L(b)	2–100	2–100	20–200	20–1200
Total alkalinity CaCO_3 , mg/L(a)	2–350	2–350	20–500	20–800
Chloride Cl , mg/L	5–1000	5–1000	1000–10000	> 10000
Sulfate SO_4 , mg/L	5–200	5–200	50–500	50–1000
Silica SiO_2 , mg/L	0.3–20	0.3–100	1–50	1–50
Total iron Fe , mg/L	0–5	0–5	0–5	0–5
Total manganese Mn , mg/L	0–2	0–2	0–2	0–2
Total phosphorus PO_4 , mg/L	0–5	0–1	0–5	0–5
Ammonia NH_3 , mg/L	0–5	0–2	0–5	0–5
Total suspended solids, mg/L	0–300	0–10	0–300	0–300

(a) These constituents are typically expressed as CaCO_3 (calcium carbonate) to facilitate calculations. (b) These constituents are either expressed as the ion (Ca and Mg) or as CaCO_3 . The use of CaCO_3 facilitates calculations.

Asiatic clams (*Corbicula fluminea*), zebra mussels (*Dreissena polymorpha*), and bryozoans are the predominant fouling species. In seawater systems, foulants consist of barnacles, oysters, hydroids, bryozoans, mussels, and others.

Corrosion Control in Service Water Systems

Techniques for controlling corrosion in service water systems consist of the addition of corrosion inhibitors to control general corrosion and the addition of biocides to control microbiological growth and prevent MIC.

Some power plants utilize corrosion inhibitors. The decision to use corrosion inhibitors is based on the severity of a corrosion problem, corrosion history, an evaluation of potential benefits, and plant economics. Once-through systems are more costly to treat than recirculating systems. The most common corrosion inhibitors for carbon steel are phosphates and polyphosphates. Often these are used in conjunction with zinc salts. Copper alloy corrosion inhibitors include filming azoles such as tolyltriazole or benzotriazole. See the article, "Corrosion Inhibitors in the Water Treatment Industry" in Volume 13A for details on treatment of water in cooling systems. Biocides for control of microbiological growth include both oxidizing and nonoxidizing biocides. Oxidizing biocides are usually chlorine or bromine com-

pounds. These act by destroying the organic material. Nonoxidizing biocides are chemicals that "kill" organisms via a metabolic mechanism. The choice of a biocide and the application mechanism depends on design characteristics, past history, economics, and environmental regulation requirements.

Deposit Control

The accumulation of deposits in piping and heat exchangers is a function of raw water and flow characteristics. In some cases, organic polymers are applied to disperse suspended solids particles and keep them moving through the system. In most cases these "silt dispersants" are low molecular weight water-soluble polymers such as polyacrylates.

Rouging of Stainless Steel in High-Purity Water

John C. Tverberg, Metals and Materials Consulting Engineers

MATERIALS OF CONSTRUCTION for equipment and piping in pharmaceutical processing plants must be resistant to corrosion from the high-purity water, the buffer solutions used in preparation of the products, and the cleaning solutions used to maintain the purity of the product. Most of the bioprocessing equipment is made of type 316L stainless steel. This alloy is selected because of its good corrosion resistance and ease of fabrication. When the buffer solutions and the final product become too corrosive for type 316L, a 6% M alloy, such as AL-6XN, 25-6Mo, or 1925hMo, is used. In very severe applications, alloys C-22 or C-276 may be used. The composition and UNS numbers of these alloys are given in Table 1.

Type 316L stainless steel is adequate for most high-purity water applications. However, under some conditions, an orange, red, magenta, blue, or black oxide coating forms on the surface. This condition is called rouging, so named because of the red variety that resembles cosmetic rouge. The orange, red, or magenta condition occurs in pure water, and the blue and black varieties appear in pure steam environments. Rouging does not appear to be a problem with the higher-nickel alloys, such as alloys C-22 or C-276. The classification of rouge and the mechanism of formation were first described in a paper given at the Validation Council's Institute for International Research seminar in 1999 (Ref 1).

Two phenomena are responsible for rouge formation: the very high purity of the water and any contaminants that may be in it. What makes high-pure water so aggressive? In its pure form,

water is nearly a universal solvent. The ionization constant for water at room temperature, $K_w = [\text{H}_3\text{O}^+][\text{OH}^-] = 1.0 \times 10^{-14}$, is very slight. However, this value increases by nearly 100 times as the temperature approaches boiling. Each of the ion groups competes for association with other ions and will react with nearly everything to satisfy this driving force. As a result, pure water is extremely reactive.

Pharmaceutical Waters

Water used in the preparation of pharmaceuticals must undergo stringent purification. The system must be validated to assure that the purity requirements are met. The three quality standards for water are the United States Pharmacopoeia (USP) (Ref 2), water for injection (WFI), and high-purity water. Corresponding clean steam is made from these waters. Table 2 presents the requirements for USP 24 pharmaceutical water (Ref 3).

The primary water used in pharmaceutical production is WFI. To qualify for WFI, the purified water (water from reverse osmosis, deionization, or softening) must pass through an evaporation stage and meet the requirements in Table 2. High-purity water is made from WFI using a second distillation.

There are various techniques for producing this water. In general, the more complete the treatment, the fewer troublesome impurities enter the WFI stream. Table 3 presents the steps for preparing WFI.

Elimination of steps in the water treatment process or poor quality control can result in deposition and corrosion problems downstream. For example, overcharging the brine softeners can result in chloride spikes that can cause pitting or crevice corrosion of the stainless steel. Elimination of the softening operation may cause calcium deposits to form on the reverse osmosis membranes. Failure to remove the chlorine and chloramines in the water can harm the reverse osmosis membranes and, under some conditions, allow chloramines to enter the WFI. Evaporation will not remove chloramine. Failure to include reverse osmosis and/or electrolytic deionization or mixed-bed deionizers in the treatment will allow volatile salts to be carried over in the preparation of the WFI. Neither a still nor a vapor compression unit will remove all of these salts. Some of the compounds that are carried over in steam are:

- Iron magnesium hydroxide silicate
- Sodium iron silicate
- Calcium silicate
- Calcium aluminum silicate hydroxide
- Magnesium octahydride silicate
- Magnesium silicate hydrate
- Sodium metasilicate
- Sodium aluminum silicate
- Sodium chlorohexaaluminum silicate
- Potassium aluminum silicate
- Potassium trisodium aluminum silicate
- Magnesium silicate hydrate
- Magnesium octahydride silicate

Silica is especially troublesome because it precipitates on stainless steel surfaces and can trap other contaminants that are in the water. Silica deposits can form concentration cells and set the stage for chloride crevice corrosion. Acid cleaning will not remove it; it must be removed mechanically. Silica is usually present as the silicate, either as an ion or when agglomerated as colloidal particles. Reverse osmosis will remove most silica, but there is a possibility of fouling the membranes. Passing the water through a series of mixed-bed deionizers effectively removes most of the silica.

Chlorides

Chloride is the primary contaminant in water that attacks stainless steel. Chloride destroys the passive layer by dissolving chromium and allowing reaction of water with iron, forming the red oxide Fe₂O₃, named hematite. The chemical reaction appears to take place in two phases. The first involves dissolution of chromium by the chloride ion; the second is oxidation of iron after the passive layer is dissolved:

According to Ref 4, “this gelatinous precipitate adheres loosely to the iron” component of the stainless steel and “influences further corrosion in two ways”: it retards corrosion “because it reduces the mobility of ions migrating to anodes and cathodes” that exist within the alloy formed by the “minute alloying elements that exist within the corrosion cell”; and it

“accelerates corrosion by blocking off certain areas of the iron from access to the oxygen.” Therefore, “oxide is removed most energetically from those areas where rust (oxide) has accumulated and the supply of oxygen is the most limited.” When this occurs, pitting usually results. This may be an explanation for the red gelatinous oxide often found in WFI systems.

Chloride can come from a number of sources: chloramines from the disinfection of the water supply, from brine used to recharge the sodium zeolite softeners, or from additives such as sodium or potassium chloride and hydrochloric acid used in the preparation of the pharmaceuticals. Figure 1 illustrates a pit in the casing of a hot WFI centrifugal pump caused by chloramine, identified using x-ray photoelectron spectroscopy.

Chloramines are formed by the reaction of hypochlorous acid and ammonia. There are three species of chloramine: monochloramine (NH₂Cl) formed above pH 7 and which predominates at pH 8.3; dichloramine (NHCl₂) formed at pH 4.5; and nitrogen trichloride (NCl₃), sometimes called trichloramine, formed below pH 4.5. Between pH 4.5 and 7, both dichloramine and monochloramine exist. They are very volatile; therefore, distillation will not remove them.

Three chloride-induced corrosion mechanisms affect stainless steel in the pharmaceutical systems: pitting corrosion, crevice corrosion, and chloride stress-corrosion cracking. Pitting and crevice corrosion are fairly common, and stress-corrosion cracking occasionally occurs in stills, heat exchangers, and hot water systems. Three charts (Ref 5) are helpful in determining the effect of chlorides on stainless steel. Figure 2

illustrates the pitting relationship between chlorides, pH, and molybdenum content. If the pH and chloride content are above the molybdenum content curves, the alloy will pit. If they are below the molybdenum content curves, the alloy is safe to use. Figure 3 is the crevice corrosion relationship between the alloy, expressed as the pitting resistance equivalent number (PREN), and the critical crevice temperature. The PREN includes nitrogen content and is related to the composition of the alloy. The PREN is equal to %Cr + 3.3%Mo + 16%N. Table 4 lists the PREN for a number of common alloys based on the minimum allowed alloy content. This relationship (Fig. 3) gives an indication of the temperature for onset of crevice

Fig. 2 Pitting corrosion as a function of chloride content, pH, and molybdenum content of austenitic iron-chromium-nickel alloys. Temperature range 65 to 80 °C (150 to 180 °F). Pitting is not a problem below the line but may be severe above the line. Source: Ref 5

corrosion, known as the critical crevice temperature. If the temperature and PREN are above the alloy type line (austenitic, duplex, or ferritic), the alloy will crevice-corrode. If it is below, the alloy is safe to use. The greater the interval between the critical crevice temperature, and the operating temperature, the greater the potential for crevice corrosion to occur. Figure 4 illustrates the probability of stress-corrosion cracking of a nickel alloy in a chloride environment. Three conditions must be met for this to take place: nickel content in the range of 6 to 25%; a residual tensile stress that exceeds the yield strength; and the proper environmental conditions of pH, chloride content, and threshold temperature. Each alloy has a threshold temperature above which it will crack but below which it will not. Table 5 lists the approximate threshold temperatures for some of the more common alloys.

Passive Layer

Stainless steels and chromium-containing nickel alloys derive their corrosion resistance from a chromium-rich passive layer. This passive layer is extremely thin, on the order of 10 to 100 atoms thick (Ref 6). It is composed mainly of chromium oxide, which prevents further diffusion of oxygen into the base metal. However, chromium is also stainless steel's Achilles heel, and the chloride ion is the problem. Chloride combines with the chromium in the passive layer to form soluble chromium chloride. As the chromium dissolves, active iron is exposed on the surface, which reacts with the environment to form rust. Alloying elements such as molybdenum minimize this reaction.

Two conditions must be met for a chromium-containing alloy to be passive (Ref 7). First, the chromium content on the surface must be greater than the iron content. Second, both the chromium and iron must be present as oxides. To meet the first condition, iron must be removed from the surface. To meet the second condition, an oxidation-reduction reaction must occur: the metals must be oxidized, and the passivating solution must be reduced. Chemical passivation is required; air passivation does not yield a stable passive layer. Today (2006), two acid combinations are used for passivation: 20% nitric acid at 20 to 50 °C (70 to 120 °F) for 30 to 60 min; and 10% citric acid + 5% ethylenediamine tetraacetic acid (EDTA) at 75 to 80 °C (170 to 180 °F) for 5 to 16 h. Technically, citric acid is not a passivating acid. It preferentially dissolves the iron, and the EDTA, a chelating agent, keeps iron ions in solution. The low-pH hot water oxidizes the chromium and remaining iron to form the passive layer, the composition of

which approximates that of chromite spinel ($\text{FeO} \cdot \text{Cr}_2\text{O}_3$). It appears that citric acid passivation treatments yield higher chromium/iron ratios in the passive layer than does nitric acid. The mechanism for nitric acid passivation is described in Ref 6 to 8.

The quality of the passive layer is normally expressed as a chromium/iron ratio. Several methods are used to measure the composition, including Auger electron spectroscopy (AES) and x-ray photoelectron spectroscopy (XPS), also known as electron spectroscopy for chemical analysis. Both methods employ sputtering with ionized argon to remove layers of atoms. This allows progressive analyses of succeeding layers of the metal and oxide film so that a composition profile, or depth profile, can be made. Both methods report the composition in atomic percent. Table 6 compares these two methods with energy-dispersive spectroscopy, sometimes called microprobe analysis. Figure 5 presents an AES depth profile of a passivated type 316L surface. In this scan the chromium/iron ratio is 1.5, indicating a passive surface. Figure 6 illustrates the depth profile of type 316L with an outstandingly high chromium/iron ratio of 7.7, as determined by XPS. By comparison, Fig. 7 shows a depth profile for a type 316L tube with an extremely poor chromium/iron ratio of 0.13. This material will rust in a humid environment.

Several terms need to be defined to understand the convention in interpreting depth profile results:

- Maximum chromium/iron ratio generally occurs at the depth where oxygen reaches its maximum concentration, usually 0.3 to 1.5 nm, or 1 to 5 atoms, from the surface
- Depth of passive layer is defined as the depth where the oxygen content is half that of the difference between the maximum and base metal content.
- Carbon content is the sum of all carbonaceous materials on the surface, including carbon dioxide, residual isopropanol from cleaning, carbonates from the water or reaction with carbon dioxide, surfactants, and any other organic compound. Most industrial materials are in the 50 to 60 at.% C range.
- Oxygen content includes that from air, occluded carbon dioxide, organic compounds, and the passive layer. The most meaningful numbers occur away from the metal surface.

Not all stainless steel strip is created equal when it comes to the passive layer. Two compositions may be essentially identical, but one may have a chromium/iron ratio of 1.5 and the other a chromium/iron ratio of only 0.2. This difference arises from the use, or nonuse, of nitric acid in descaling the strip. If the strip is descaled using a nitric-hydrofluoric acid bath, the chromium/iron ratio will be high. If the strip is grit blasted or descaled in a sulfuric-hydrofluoric acid bath, the ratio will be low. It

Fig. 5 Auger electron spectroscopy depth profile of a type 316L stainless steel surface. The exposed metal surface is on the left, and the composition with depth from the surface changes as one moves to the right. The base metal composition is reached at approximately 12.5 nm, or 35 atoms, from the surface. In this example, the chromium/iron ratio is 1.5.

Fig. 6 X-ray photoelectron spectroscopy depth profile of a type 316L stainless steel surface. The base metal composition is reached at approximately 35 nm, or 100 atoms, from the surface. In this example, the chromium/iron ratio is 7.7, an outstanding value.

Fig. 7 X-ray photoelectron spectroscopy depth profile chart of a type 316L stainless steel surface with an extremely poor chromium/iron ratio of only 0.13. This material will show rust in only a few hours in a humid environment.

appears that starting with a low chromium/iron ratio condemns the finished part to a continued lifetime with a low chromium/iron ratio.

Surface Finish

Pharmaceutical equipment is normally specified with either mechanically polished or electropolished surfaces. Mechanically polished surfaces are either 0.635 or 0.508 μm (25 or 20 $\mu\text{in.}$) R_a (average roughness), and electropolished surfaces are either 0.381 or 0.254 μm (15 or 10 $\mu\text{in.}$) R_a . Figure 8 illustrates a mechanically polished surface with a 0.508 μm (20 $\mu\text{in.}$) R_a finish. Polishing debris is seen in the grit lines, and metal laps fold over some of the grit lines. This debris leads to rouging of the system. Figure 9 is the same surface after a hot nitric acid passivation treatment. Much of the debris is gone, and many of the laps have been dissolved. Figure 10 is a much finer polish, 0.203 μm (8 $\mu\text{in.}$) R_a , that shows finer grit lines with occluded polishing debris. An electro-

Fig. 8 Mechanically polished surface with a 0.508 μm (20 $\mu\text{in.}$) R_a finish. The dark deposits in the grit lines are residual polishing debris. This debris typically leads to class 1 rouging of the stainless steel surfaces. SEM; original magnification 500 \times

polished surface is depicted in Fig. 11. This surface is very smooth; in fact, it is possible to see the grains. The white specks in this micrograph are pits where manganese sulfide inclusions were dissolved during electropolishing. Because this material was purchased to the American Society of Mechanical Engineers biopharmaceutical equipment requirements, the sulfur content was approximately 0.012%.

All surface finishes should receive a nitric acid passivation, even electropolished surfaces. This treatment has two benefits: it raises the chromium/iron ratio and removes surface contaminants. Table 7 presents data obtained from different surface finishes and with various passivation techniques. Although citric acid passivation tends to yield higher chromium/iron ratios, it does not dissolve as much polishing debris from the grit lines.

Rouge Classification

Rouge is iron oxide. The different colors result from different valences and degrees of hydration. If rouge absolutely is not allowed, the alloy of

Fig. 10 Mechanically polished surface with a profilometer reading of 0.203 μm (8 $\mu\text{in.}$) R_a . Note the polishing debris in the grit lines. SEM; original magnification 500 \times

construction should be changed to one that contains little or no iron. Not all rouge is the same, and its formation differs accordingly. There are three general classes of rouge.

Class 1 Rouge. These oxides originate elsewhere in the system and are deposited on stainless steel surfaces. They generally are held onto the surface by electrostatic attraction. The chromium/iron ratio under the deposited oxides is unaltered from that of the original passivated stainless steel. Usually, they can be removed by wiping or ultrasonic cleaning. The chemical form is Fe_2O_3 (hematite) or one of the hydroxides. Sources include erosion and/or cavitation from pump components or spray balls, residual debris from mechanical as-polished surfaces, corroding iron components in the system, and deposition from iron held in solution in the water. Metal particles from polishing debris are oxidized in the WFI and deposited on the surface. The particles and/or oxides have a composition that matches that of the stainless steel from which they originated, for example, polishing debris or particles from the pump impeller.

The lowest valence state for class 1 rouge is the yellow-orange oxide $\text{FeO}(\text{OH})$, hydrated ferrous oxide. According to Ref 9, this form corresponds to the mineral limonite, which is yellowish-brown to orange in color. Its formation can be chemically stated as:

According to Ref 10, “rusting occurs only if both oxygen and water are present. Iron will not rust in dry air or oxygen-free water.” Therefore, oxygen must be present in the WFI, or a corrosion cell must be present to liberate oxygen at the anode.

The following reaction is the oxidation of the hydrated ferrous oxide to ferric oxide (Fe_2O_3) to produce the red or magenta color:

Alternatively, the reaction could be:

These reactions allow oxidation to a higher valence state without a decrease in pH by formation of gaseous molecular hydrogen. According to Ref 9, the red oxide hematite can exist in several forms: an “earthy” form, usually

amorphous, and a crystalline form. Its crystalline form is rhombohedral. It can exist as crystals, specular hematite, compact columnar, or fibrous. When chromium is present, it can be octahedral and is a form of chromite spinel ($\text{FeO} \cdot \text{Cr}_2\text{O}_3$). When nickel is present, it is called trevorite ($\text{NiO} \cdot \text{Fe}_2\text{O}_3$), also octahedral. Figure 12 illustrates the general form of the orange amorphous deposit. When examined at higher magnification (Fig. 13), this amorphous-appearing deposit has a rhombohedral crystal form. Figure 14 illustrates the growth of crystals in the polishing striations and on the surface. These are the areas that had deposits of polishing debris. Figure 15 illustrates twinned rhombohedral crystals attached to the surface but not appearing to be growing on the surface. The twinned structure may be growing by taking iron from the water.

Class 2 Rouge. This type of rouge forms in situ on the stainless steel surface. By its formation, the chromium/iron ratio is altered, usually decreased by dissolution of the chromium and formation of ferrous/ferric hydroxide/oxide, usually Fe_2O_3 . There are at least two subclasses of class 2 rouge.

Fig. 12 Class 1 rouge that is transported from other locations and deposited on the stainless steel surface. It is amorphous in structure, and the color varies from orange to red. The primary mineral form is hematite, Fe_2O_3 . SEM; original magnification 450×

Fig. 13 Highly magnified view of the amorphous class 1 rouge crystals. They appear to be rhombohedral in form. SEM; original magnification 20,000×

Class 2A. This forms in the presence of chlorides. This type of rouge can be removed only by chemical or mechanical means. The chromium/iron ratio under the rouge approaches that of the base metal composition, and tubercles or crystal growths are observed on the surface. The metal surface under the tubercle, when removed, is bright silver, representing an active corrosion site. Figure 16 illustrates rouge that grows in the presence of chloride. The corrosion mechanism was described earlier. Figure 17 illustrates acicular crystals growing from the surface, possibly from chloride micropits. Rhombohedral crystals can then grow from these seeds, using the iron from the metal or from that in the water. Figure 18 illustrates the fibrous structure that develops from the acicular crystals.

Class 2B. This rouge forms on unpassivated or improperly passivated surfaces where the passive layer is inadequate to prevent the diffusion of oxygen to the metal below the passive layer. Both the thickness of the passive layer and the chromium/iron ratio have an effect. A classic example is air passivation of a mechanically abraded surface. Such a passive layer is on the order of 1 nm (3 atoms) thick and is easily

Fig. 14 Rhombohedral crystals forming on the surface of a mechanically polished tube with a high chromium/iron ratio. This appears to be class 1 originating from polishing debris. Note the high density of small crystals in the polishing striations. SEM; original magnification 450×

Fig. 15 These twinned rhombohedral crystals do not appear to be growing on the surface. They are associated with residual polishing debris. Class 1 rouge. SEM; original magnification 7500×

Table 7 Comparison of type 316L chromium/iron ratios using various polishing and passivation techniques

Polishing method	Chromium/iron ratio
Electropolish, no passivation	0.8
Electropolish, nitric passivation	1.8
Electropolish, citric passivation	2.5
Heavy mechanical polish, no passivation	0.3
Heavy mechanical polish, nitric passivation	0.8
Heavy mechanical polish, citric passivation	1.1
Light mechanical polish, no passivation	0.33
Light mechanical polish, nitric passivation	1.0
Light mechanical polish, citric passivation	1.4

destroyed. By comparison, a properly electropolished and chemically passivated surface may be over 30 nm thick. The formation of class 2B rouge is strongly influenced by the surface preparation of the stainless steel. Tuthill and Avery (Ref 11) subjected different metal surfaces to high-purity water. They found that mechanically polished surfaces without passivation had the most iron dissolved in the water, and properly passivated electropolished surfaces had none. Table 8 is a summary of their findings. Figure 19 illustrates crystals attached to a stainless steel surface with a lower chromium/iron ratio.

Class 3 Rouge. This rouge forms in the presence of high-temperature steam, usually above 120 °C (250 °F). The color is black. The chemical composition is totally different from that of class 1 or class 2 rouge: Fe₃O₄ rather than Fe₂O₃. The mineralogical classification is magnetite rather than hematite, and the morphology is decidedly crystalline on both the substrate and the crystals projecting above the substrate.

The black color is due to the formation of iron sesquioxide (Fe₃O₄), or magnetite. According to

Ref 9, this oxide is commonly, if not always, formed under conditions of high temperature. It is of the form FeFe₂O₄ or FeO·Fe₂O₃, in which the ferrous iron occasionally may be replaced with nickel, forming trevorite (NiO·Fe₂O₃). Reference 4 states that “this oxide is formed at very high temperatures by the action of air, steam, or carbon dioxide upon iron.” The reaction involves two oxidation steps:

The two oxides coexist in the same octahedral unit cell because of the limited diffusion of oxygen.

There are three subclassifications of this rouge form, depending on the nature of the stainless steel surface.

Class 3A. This form of rouge occurs on properly passivated and electropolished surfaces. Its appearance is glossy black, very adherent (cannot be rubbed off), very stable, and can be removed only by chemical dissolution or mechanical abrasion. It forms at higher steam temperatures, usually above 150 °C (300 °F). It completely covers the surface with continuous crystals, as Fig. 20 illustrates. The crystals probably contain chromium, because both mag-

netite and chromite are octahedrons and both form the spinel class of minerals.

Class 3B. This form of rouge occurs on unpassivated or mechanically polished surfaces and at lower temperatures, usually in the range of 105 to 120 °C (220 to 250 °F). Its appearance is powdery black, sometimes with sparkles. It can be rubbed off but can be completely removed only by chemical dissolution or mechanical abrasion. It is magnetite or chromite spinel.

Class 3C. This form of rouge forms on surfaces subjected to high-temperature or hot electrolytic solutions. It is a precursor to either class 3A or 3B rouge. The color is iridescent gold, red, or blue. The color is related to the oxide thickness (Ref 12). Figure 21 illustrates the depth of oxygen as a function of color. The control is the standard silver electropolished film, the gold color is the fully oxidized chromite spinel, and the blue is the onset of magnetite formation.

Castings

Castings have a highly variable surface, depending on the amount of mechanical polishing. Cast type 316L stainless steel is designated

Fig. 16 Class 2A rouge that forms in the presence of chlorides. When the tubercles are broken off, a bright silver spot is under them, indicating an active chloride corrosion cell. SEM; original magnification 450×

Fig. 17 Acicular crystals growing from the surface of stainless steel exposed to chloramines at steam temperatures. The acicular crystals appear to be growing from the surface of the stainless steel, perhaps from a chloride micropit. They appear to be the start of class 2A rouge. The large rhombohedrons may be from polishing debris or may have grown from dissolved iron in the water. SEM; original magnification 5000×

as CF-3M. The cast version has lower manganese and nickel and higher chromium and silicon than the wrought version. This promotes a higher delta-ferrite content in the casting. In general, the silicon content is at its maximum, 1.5%, to promote greater fluidity of the molten metal. This high silicon content further promotes the formation of delta ferrite. Delta ferrite is the high-temperature form of the iron-rich compound that solidifies first from the melt, forming the basic dendritic structure. Normally, a skin of ferrite that is low in chromium and high in silicon and iron is formed on the casting. If the delta-ferrite content of the casting is less than 8%, as determined from the DeLong-Schaeffler (Ref 13) or Welding Research Council (Ref 14) diagrams,

the ferrite can be dissolved by a long-term solution anneal. If the heat treatment is inadequate or if the ferrite content is greater than 8%, ferrite remains in the structure. Ferrite will corrode preferentially, resulting in pits on the surface. If machining or grinding, as in the case of valve components, removes the high-ferrite skin, the substrate surface composition becomes the nominal composition of the alloy. A high chromium/iron ratio results (Fig. 22) if this surface is electropolished and passivated.

Investment casting is used to produce complex shapes such as pump impellers. Because the surface is so smooth, little or no grinding is performed; the surfaces are simply buffed. The ferrite-rich skin is not removed, and the resulting chromium/iron ratio is very low, 0.06 (Fig. 23). Such a surface will be subject to corrosion and cavitation/erosion and will be a source of class 1 rouge. Figure 24 illustrates the surface of an impeller vane that has been subjected to cavitation and/or erosion. The delta-ferrite ridges (the white phase) stand in relief because they represent the harder material, and the interdendritic austenite (the dark phase) has eroded away.

Fig. 22 Depth profile for a CF-3M (type 316L) casting that has been machined, electropolished, and nitric acid passivated. The chromium/iron ratio on the surface is 4.1.

Fig. 23 Depth profile for an investment cast pump impeller that had essentially no metal removed from the surface. The chromium/iron ratio is low (0.06), and the metal does not meet nominal composition until a depth of 350 nm is reached. This surface will be subject to corrosion and cavitation/erosion. It can be a source of class 1 rouge in the system.

Cleaning and Repassivation

Badly rouged surfaces should be acid cleaned. Class 1 rouge needs to be removed with a mild citric acid + EDTA solution. Class 2 rouge should be taken to bare metal with a primary cleaning using oxalic acid, formic acid, or ammonium bifluoride, followed with a passivation treatment using citric acid + EDTA. Class 3 rouge is different. Once it forms, it is best to leave it alone. An alternative procedure is to clean with citric acid to remove any occluded iron oxides.

When should one repassivate? The only way to know the condition of the passive layer is to perform a depth profile analysis. This is a destructive test, requiring approximately 1 cm² (0.16 in.²) material from the system. This material can come from a spool piece, a blind flange, or any component, except a casting, that has been exposed to the environment and has been part of

Fig. 24 Investment cast impeller surface roughened by cavitation/erosion in water for injection service. The white ridges are harder delta ferrite, and the dark areas are the softer interdendritic austenite. Original magnification 100×

the system since the original passivation. In general, if the surface has not been altered or compromised since the original passivation, it is not necessary to repassivate. This includes class 1 rouge. The surface can be derouged using citric acid, but it does not need repassivation. The difference in these two treatments is time. Derouging is rather fast, whereas passivation is a long-term process. Class 3A rouge should never be removed, because the only way to remove it is to use very harsh reagents that will destroy the surface finish and passive layer. In addition, it will form again in several months, probably as unstable rouge.

The surface should be cleaned and repassivated under these conditions:

- New components have been added to the system.
- Welding has taken place anywhere in the system.
- Class 2A rouge is present.
- Class 2B rouge is present.
- Class 3B rouge is present under some conditions.

Class 3B should be addressed if the surface was not passivated or if the original passivation was not adequate. The only way to determine if the passivation was inadequate is to perform a depth profile analysis.

Summary

To prevent or at least minimize rouge formation in WFI, high-purity water, or clean steam systems, the following procedures should be followed:

- Use and maintain the best water treatment process available to produce the best-quality water possible. Maintain a water database that charts the critical elements. The incoming water database, up to the deionizer, should include, as a minimum, calcium, iron, magnesium, manganese, silicon (silica), copper, zinc, aluminum, chloride, dissolved solids, pH, temperature, conductivity, and the Langelier saturation index. These values can be reported in parts per million (ppm or mg/L).

The deionized, reverse osmosis, WFI, high-purity water, and clean steam condensate should be analyzed for calcium, potassium, iron, nickel, chromium, chloride, silicon, magnesium, manganese, aluminum, copper, zinc, conductivity, pH, and temperature. These values should be reported in parts per trillion (ppt) and updated monthly.

- Use electropolished components wherever possible. Specify the components to be passivated at the factory, using nitric acid.
- Use care during welding to prevent heat discoloration on the heat-affected zone. Discoloration, at the worst, should be a light straw color. Ideally, the heat-affected zone should be silver.
- Thoroughly clean and passivate the system prior to start-up. This will passivate the welds in the system.
- Use proper design and installation practices for all piping systems. This includes positive drain angles, not placing reducers in the inlet to centrifugal pumps, proper steam traps, elimination of dead legs, and so on.
- Choose the alloy of construction based on the nature of the product to be contained in the lines, vessels, and other components, not based on the price. Use Fig. 2 to 4 to aid in making the proper selection.
- Make certain that no iron, brass, copper-nickel, or other materials that corrode easily are in the system.
- Use submicron filters where critical operations take place.

Corrosion in Wastewater Systems

Jose L. Villalobos, V&A Consulting Engineers
Graham Bell, M.J. Schiff & Associates

METALLIC AND CONCRETE STRUCTURES and equipment at wastewater treatment plants are exposed to corrosive environments that can lead to corrosion, degradation, and ultimately failure (Ref 1). Options are available for eliminating or minimizing corrosive impacts arising from these exposures, including proper materials selection, coatings, and electrochemical methods, such as cathodic protection. It is also possible, in some cases, to modify the environment to make it less corrosive.

Predesign Surveys and Testing

The environments in wastewater treatment plants can be classified as buried, fluid, and atmospheric exposures.

Soil Testing. Prior to the detailed design of a wastewater treatment plant or construction of new capital improvement projects, a corrosion survey should be performed at the project site. This survey should include soil resistivity testing, chemical analysis of soil and/or water samples, and inspection of any facilities that may already exist at the proposed treatment plant location. An investigation should be conducted to determine if existing cathodically protected utilities are located at the proposed project location. In situ soil resistivity measurements should be made in a grid pattern at distances that will provide representative data. The testing intervals should not exceed 300 m (1000 ft) in either direction and to the excavation depth. Soil samples should be collected at representative locations and at locations of low soil resistivity for chemical analysis and laboratory resistivity testing. Half-cell potential surveys and current requirement testing should be performed at locations where cathodic protection will be installed on existing facilities. Data regarding the interpretation of soil properties for the development of corrosion control strategies are available in several recent publications (Ref 2–4).

Testing of the wastewater to be transported is critical for materials selection and corrosion control for submerged exposures and vessel interiors. Many of the same parameters determined

for soils should be determined for water or other fluids to be transported or contained. These include pH, chloride ion content, and resistivity. Other parameters to be investigated include dissolved oxygen, the biochemical oxygen demand, the chemical oxygen demand, levels of suspended solids, and the Langelier saturation index.

Dissolved oxygen (DO) is the oxygen dissolved in water, wastewater, or other liquid, usually expressed in milligrams per liter (mg/L) or parts per million (ppm).

Biochemical oxygen demand (BOD) is the quantity of oxygen used in the biochemical oxidation of organic matter in a specified time (5 days, unless otherwise indicated) and at a specified temperature.

Chemical oxygen demand (COD) is a measure of the oxygen-consuming capacity of both organic and inorganic matter present in water or wastewater. It is expressed as the amount of oxygen consumed by this matter in a specified test (Ref 5).

The Langelier index gives an indication of the tendency of a fluid to deposit minerals on the interior surfaces of pipelines or to corrode the interior surfaces of the pipeline. A negative value for this index, less than -0.5 , is indicative of a corrosive environment, whereas a positive index, greater than 0.5 , indicates a tendency for calcium carbonate scale to form.

Atmospheric Testing. Wastewater treatment plants are situated in marine, industrial, and rural atmospheric environments. In marine atmospheric environments, the combination of wet/dry cycling in the presence of chlorides found in airborne salts creates the potential for significant atmospheric corrosion activity on all exposed metal surfaces. In addition to marine exposures, plant processes and sanitary sewers are likely to generate airborne substances, such as hydrogen sulfide, that will also be deleterious to metallic and concrete structures. The proximity of wastewater treatment plants to major highways and industries may expose materials at the plant to high levels of sulfur dioxide that can cause corrosion of certain metals and deterioration of coating systems. Testing should be conducted for relative humidity values,

atmospheric salt content, and hydrogen sulfide (Ref 6).

Hydrogen Sulfide Testing. Levels of suspended solids, DO, BOD, and COD affect the ability of wastewater streams to produce hydrogen sulfide. Hydrogen sulfide, when oxidized, will degrade concrete and corrode exposed steel. Hydrogen sulfide gas is generated after the available oxygen in the wastewater is depleted by aerobic (oxygen-consuming) bacteria. Once the oxygen is depleted, anaerobic (nonoxygen-consuming) bacteria, also present in the wastewater, become active. Under these conditions, the anaerobic bacteria reduce sulfate to hydrogen sulfide. Most of the production of hydrogen sulfide occurs in the slime layer that coats the submerged pipe walls of sewer pipelines. The anaerobic bacteria also metabolize sulfur from proteins and other elements found in the wastewater. Most wastewater carries large quantities of sulfur compounds (Ref 7).

Once hydrogen sulfide is formed, it remains concentrated in the wastewater until the saturation level is reached. At the saturation level, the hydrogen sulfide is released from the wastewater and enters the airspace inside the sewer above the waterline. Another group of aerobic bacteria, which lives on the walls of the sewer above the flowline, reacts with hydrogen sulfide and oxygen to form sulfuric acid. Sulfuric acid is corrosive to steel, concrete, and copper. The following terms are important for understanding and analyzing the conditions for generation of hydrogen sulfide.

Dissolved Sulfide. The sum of all sulfur species, that is, sulfide, hydrosulfide, and hydrogen sulfide, measured in a wastewater sample collected in the field, using a LaMotte Pomeroy test kit, is referred to as the dissolved sulfide.

Total Sulfides. The sum of soluble and insoluble sulfur species is referred to as total sulfides. Total sulfides are measured in the field from a wastewater sample collected from the sewer system using another version of the LaMotte Pomeroy test kit. The measurement of total sulfides in the field indicates the magnitude of the sulfur species present in a wastewater.

Sulfide Generation. The primary parameters that influence the production of sulfides within

the piping system that transports the wastewater to the treatment facility are:

- **Temperature of the wastewater:** As the temperature increases, the rate of biological reactions increases, and the concentration of sulfides will also increase.
- **Dissolved oxygen concentration:** As DO increases in the wastewater, the concentration of sulfides will be reduced. A DO concentration of approximately 1 mg/L is generally adequate to keep the concentration of total sulfides to less than 1 mg/L.
- **Wetted surface area:** As the depth of wastewater increases in a sewer pipe, the wetted surface area of the pipe is also increased. This wetted surface area is the location of the sulfide-producing microorganisms. As the wetted surface area increases, so does the number of microorganisms within the pipe, which in turn increases the total sulfides that are generated.
- **Sewer slopes:** A less sloped sewer pipeline will reduce the flow velocity, which increases sedimentation and diminishes the rate at which oxygen becomes dissolved in the wastewater. This promotes anaerobic conditions and provides microorganisms with ample time and nutrient to feed and generate sulfide. Hydraulic conditions that cause splashing or hydraulic jumps promote the release of hydrogen sulfide.

Material Considerations

Materials selection is based on many engineering and economic parameters in addition to corrosion resistance. The corrosion performance of these materials in the various environments follows.

Concrete pipes, basins, and tanks are common in facilities.

Soil Exposure. Concrete is typically a durable material in underground service. Unlike metals, it is rarely affected by electrolytic corrosion. Attack on concrete is likely when soils are acidic. Barrier coatings may be required to protect concrete surfaces in low-pH environments. In areas of high water-soluble sulfate ion concentrations, modification of the water-cement ratio and use of type V cements (sulfate resistant), admixtures, and barrier coatings should be considered for all buried concrete structures.

Fluid/Atmospheric Exposure. Concrete structures can be attacked by biologically formed sulfuric acid. Sulfuric acid formation is greatest where hydrogen sulfide is readily available and where aerobic conditions and moisture are present to oxidize the sulfides to sulfuric acid. These conditions exist where biological slimes are present on the pipe walls and where aerobic conditions and moisture exist above the wastewater flow.

Wastewater contains a variety of sulfates in solution. Sulfate-reducing bacteria present in wastewater convert these sulfates to sulfides and

related compounds. Dissolved sulfide concentrations of 0.4 ppm in the waste streams are considered detrimental. Some of these sulfides are released from solution into the airspace over the water surface. Aerobic bacteria, commonly found in the crown of sewers or in the top of structures such as wet wells, can then convert the hydrogen sulfide to sulfuric acid. Concrete is severely attacked by sulfuric acid. Rapid destruction of the concrete and subsequent exposure of the aggregate and reinforcing steel can occur. A typical example of hydrogen-sulfide-induced corrosion that has progressed to the point of exposing the reinforcing steel in a gravity sewer pipe is shown in Fig. 1.

The use of bare concrete is not recommended at locations where high hydrogen sulfide concentrations may occur. These areas include channels, manholes, wet wells, and surfaces of structures that are not exposed to the atmosphere, such as interior pipe surfaces and covered digesters. Protection of the concrete with a polyvinyl chloride sheet lining ensures the durability of structures, both on the submerged surfaces and within the airspace above the fluid surface. This is particularly vital when submergence varies, continuously exposing the surface to wet and dry conditions. Reinforced concrete structures are subject to cracking and spalling due to corrosion of reinforcing steel. Because the volume of corrosion product is much greater than that of the reinforcing steel itself, great pressure is exerted on the concrete, which may cause it to crack and eventually spall. Sewage pumping stations are especially susceptible to this type of corrosion activity.

Fig. 1 Exposed reinforcing steel in gravity sewer pipe

Exposure of concrete surfaces to chlorides and hydrogen sulfide should be minimized through the use of coatings.

Steel and Ductile Iron. For all exposures, steel and ductile iron should be electrically isolated from dissimilar metals to prevent the formation of galvanic corrosion cells.

Soil Exposure. Low resistivities and high chloride concentrations in the soil may lead to corrosion of buried steel and ductile iron pipelines or structures. Cathodic protection should be considered for all buried steel and ductile iron pipelines or structures. Where cathodic protection is not provided, corrosion-monitoring equipment should be incorporated into the design to allow the operating staff to monitor the condition of the pipelines or structures. Non-welded joints must be bonded for electrical continuity.

Steel and ductile iron structures should be well coated, and where the potential for corrosion is high, based on resistivity and soil chemical analysis, they should be cathodically protected.

Fluid Exposure. Steel and ductile iron are subject to corrosion when exposed to fluids at a wastewater facility. Corrosion of steel and ductile iron is most severe in the splash zone, where atmospheric oxygen hastens the corrosion process. Submerged steel and ductile iron should be coated with a material suitable for use in immersed exposures. Figure 2 illustrates a sample of a submerged steel structural member that has lost the protection provided by the coating system. Due to the corrosive nature of the wastewater treatment process streams, cathodic protection can be an effective means of corrosion control of steel and ductile iron surfaces. Cathodic protection should be used in combination with suitable coating systems.

Atmospheric Exposure. Corrosion of steel and ductile iron structures exposed to the atmosphere at wastewater facilities is likely due to atmospheric chloride and hydrogen sulfide levels. Hydrogen sulfide attacks metallic surfaces rapidly. Uncoated steel and ductile iron will not endure in outdoor ambient conditions

Fig. 2 Delaminating coating on steel rake arm

where hydrogen sulfide is present and are usually coated in less harsh atmospheres as well. Steel and ductile iron structures of particular concern, such as floating digester covers, must be coated.

Aluminum is a part of structures and indoor and outdoor equipment.

Soil Exposure. Aluminum is not recommended for underground applications. Soil becomes more aggressive to aluminum as moisture and dissolved salt levels increase. Contact with elevated levels of chlorides and sulfates or low-pH environments will be detrimental to buried aluminum. Dry, sandy, and well-aerated soils are less likely to be corrosive to aluminum.

Fluid Exposure. Aluminum is attacked by both acids and bases. When exposed to fluids, aluminum is most stable in the pH range from 4 to 8.5. Contact with solutions with pH greater than 8.5 or less than 4 will cause corrosion of the aluminum.

Severe pitting of aluminum can occur where iron or copper ions are in a solution in contact with aluminum. A galvanic couple is established, and aluminum is attacked at localized areas. Chloride ions can also lead to pitting of aluminum. Pitting is most likely to occur in crevices, welds, and other stagnant areas. The introduction of chemicals, such as ferric chloride, into the process stream may cause severe degradation of aluminum, and failure could occur rapidly. Aluminum is not recommended for use in fluid exposures, due to the wide range of pH values found in wastewater facilities.

Atmospheric Exposure. Aluminum has excellent resistance to atmospheric sulfides and other pollutants due to a tightly adherent oxide film. Destruction of the oxide film will expose a very reactive surface. If the protective oxide film is disturbed, the presence of salts, including chlorides, can cause rapid pitting of aluminum. Nonanodized aluminum can suffer severe corrosion in marine environments. Electrical coupling to iron, stainless steel, or copper will accelerate the deterioration of aluminum.

Aluminum is stable only in a band of pH values. Aluminum handrails to be installed in concrete (pH 12 to 13) should be placed in plastic shields that are cast into the concrete. In addition, a sealant should be placed between the plastic shield and the aluminum. Under these conditions, aluminum will provide acceptable performance. Aluminum is not recommended in areas where contact with chlorine, sodium hydroxide, and other strong acids and bases may occur.

Anodized aluminum has shown excellent performance in limited applications at wastewater facilities. Anodized aluminum is recommended for use in areas such as electrical switchgear enclosures.

Aluminum is an electrically active metal (potential of -1.66 V versus standard hydrogen electrode); therefore, its use in water is limited. If coupled to any of the common engineering alloys (steel, iron, stainless steel, or copper and its alloys), aluminum will become the anode and

will galvanically corrode. Aluminum must be electrically isolated from dissimilar materials.

Copper and brass are often used for potable water lines and fittings and in most electrical equipment.

Soil Exposure. Copper and brass typically perform quite well in underground applications where the pH is neutral to alkaline and the concentration of aggressive ions, such as chloride and sulfate, is low. Electrical isolation of copper from most materials commonly used in wastewater plant construction is required in buried service.

Copper is subject to changes in corrosion resistance with changes in temperature. Electrolytic corrosion can occur on hot and cold water lines buried in a common trench. To prevent corrosion, the two lines should be electrically isolated from each other. Electrical isolation can be accomplished with the use of insulating-type couplings. Copper or brass piping should not be used without a tape wrap coating and cathodic protection in environments where high chloride concentrations, high sulfate concentrations, and low pH values are present. Copper or brass should be electrically isolated from other structures if used in an aggressive environment. Connections of copper service lines to plastic mains should be accomplished using brass tapping saddles.

Fluid Exposure. Copper and brass may be subject to corrosion in wastewater environments. The presence of sulfides and ammonia compounds in the wastewater can lead to dissolution of cuprous compounds. If copper is coupled to a less noble metal, such as steel or aluminum, galvanic corrosion of the less noble metal may result. Because copper is a fairly soft material, it is also subject to erosion-corrosion, that is, accelerated by high fluid velocities, high temperatures, and abrasive particulate matter.

Copper and brass should not be used in any process flow stream that will allow exposure of the metal to solutions carrying residual chlorine (2 ppm or more). This is especially critical in reclaimed water systems, because chlorine can cause severe corrosion of copper and brass. Any process stream containing more than 0.1 ppm of hydrogen sulfide should be prevented from contacting copper or brass. Brasses containing over 15% Zn may suffer dezincification. Dezincification is especially prevalent in stagnant, acidic solutions.

Atmospheric Exposure. Copper and brass typically have excellent atmospheric corrosion resistance; however, they are actively attacked by hydrogen sulfide. Due to the probability of the presence of hydrogen sulfide in the atmosphere at a wastewater treatment plant, copper and brass should not be used without protective coatings. Because it may be impossible to eliminate the use of copper alloys, particularly in electrical systems such as switches and fuses, extreme care should be taken to prevent rapid deterioration of these items.

One means of reducing corrosion of copper and brass is to use conduits and sealed junction

boxes (typically, National Electrical Manufacturer's Association type 4X). These boxes should be constructed of either stainless steel or a noncorroding, nonmetallic material (e.g., glass-reinforced plastic, polycarbonate, or polyester). Conduit entrances should be sealed tightly to the boxes, and conduits themselves should be internally sealed to prevent transmission of corrosive gases between boxes. Vapor corrosion inhibitors may also be required in certain applications. Additional protection may be provided by the use of spray- or dip-type corrosion-inhibiting coatings.

Stainless steel is available for piping, enclosures, and apparatuses for harsh environments.

Soil Exposure. Stainless steel is most often used in situations where protection from contamination of the material carried in the pipe is the prime concern. Generally, stainless steel should not be used in a buried exposure in wastewater treatment plants. Stainless steel pipe derives its corrosion resistance from a tough oxide coating on the surface of the pipe. Direct burial of the pipe, even in reasonably aerobic soils, presents the threat of differential oxygen corrosion cells. Therefore, if stainless steel is to be directly buried, it should be installed with a carefully placed uniform backfill.

Fluid Exposure. Stainless steel is typically resistant to corrosion in flowing waters. The austenitic grades (300 series) of stainless steel typically have the best performance. Type 316L (UNS S31603) alloy has provided the best overall performance in most wastewater treatment plant exposures. Pitting of stainless steel may occur in stagnant or slow-moving water. Oxidizing metal salts, such as ferric chloride, may also attack stainless steel. Type 316L alloy is more resistant to chlorine, hypochlorous acid, and hypochlorite ions than other alloys that may be used in the process streams. Type 316L stainless alloy is also resistant to hydrogen sulfide and other organic materials likely to be found in wastewater environments.

Cathodic protection of stainless steel is an option for preventing pitting. Pitting has been encountered in many aqueous environments. By electrically coupling stainless steel to a large immersed structure made of steel, zinc, or other metal that is more anodic to stainless steel, pitting will be reduced or eliminated. Stainless steel will increase the magnitude of corrosion deterioration of the structure to which it is bonded. Electrical contact should be eliminated where the anode/cathode ratio is not favorable, that is, small anode to large cathode.

Atmospheric Exposure. Stainless steel has been used successfully in both outdoor and indoor applications. Of the various types of stainless steel, the austenitic grades (typically, 302, 304, and 316) generally have the best corrosion resistance. Type 316 alloy—although more expensive than the others—is the most resistant to pitting. Overall, stainless steel has demonstrated excellent corrosion resistance in severe atmospheric environments.

Fig. 3 Corroded roof vent

Coatings used for wastewater facilities must be resistant to moisture, atmospheric sulfides, sunlight, and atmospheric chlorides. Several generic coating types are available (Ref 8, 9). Generic coating types include alkyds, coal tar epoxies, zinc-rich coatings, polyester resins, polyurethanes, and urethanes. All coatings must meet local, state, and federal air quality regulations. The manufacturer's recommendations for surface preparation should be strictly followed to ensure a quality coating system.

Soil Exposure. Coatings for service in soil must be abrasion resistant, must be suitable for long-term exposure to moisture, and must have excellent dielectric properties. Coal tar epoxy and tape wrap are good coatings for ductile iron, steel, and other metallic materials. These coatings may be applied in the field; however, they are typically shop-applied. Cathodic protection may also be used in conjunction with coatings on steel and ductile iron pipe. Cathodic protection

may provide corrosion protection to the pipeline at areas of coating damage and coating imperfections. The use of a coating will reduce the current requirements of the cathodic protection system.

Fluid Exposure. Coating of structures is an effective means of protecting the structure from corrosive environments typically found in wastewater facilities. Coating of concrete structures in contact with the process flow can prevent corrosion caused by sulfuric acid in the splash zone. Coating of metal structures can reduce or eliminate corrosion due to galvanic coupling and exposure to corrosive chemicals commonly found in wastewater facilities.

For severe chlorine service, as in a chlorination apparatus, elastomeric urethanes or high-solids epoxy coatings on steel provide good service. These coatings are available in a number of colors and are resistant to chlorine solutions. Urethane coatings form a glossy, tough, attractive surface with excellent abrasion resistance and high resistance to water and effluent chemicals.

High-performance polymorphic resin coatings are also available. Polymorphic resin coatings are based on a polyester resin and cure extremely quickly. They are resistant to chemicals and are suitable for application on concrete.

Atmospheric Exposure. Coatings for atmospheric service should be specified to provide corrosion control and easy maintenance. Coatings for interior piping, equipment, and metalwork should be high-solids epoxies. Coatings for exterior service should be aliphatic polyurethanes to provide long-term corrosion protection and color retention. As illustrated in Fig. 3, corrosion due to atmospheric exposures at roof vents is a common occurrence on water and recycled water storage tanks. Each of these coatings systems has excellent resistance to chemical and process spillage.

Corrosion in Seawater

Stephen C. Dexter, University of Delaware

ALTHOUGH SEAWATER is generally considered to be a corrosive environment, it is not widely understood just how corrosive it is in comparison to natural freshwaters. Figure 1 shows the corrosion rate of iron in aqueous sodium chloride (NaCl) solutions of various concentrations. The maximum corrosion rate occurs near 3.5% NaCl—the approximate salt content of average full-strength seawater (Ref 1).

The general marine environment includes a great diversity of subenvironments, such as full-strength open ocean water, coastal seawater, brackish and estuarine waters, bottom sediments, and marine atmospheres. Exposure of structural materials to these environments can be continuous or intermittent, depending on the application. Structures in shallow coastal or estuarine waters are often exposed simultaneously to five zones of corrosion. Beginning with the marine atmosphere, the structure then passes down through the splash, tidal, continuously submerged (or subtidal), and subsoil (or mud) zones. The relative corrosion rates often experienced on a steel structure passing through all of these zones are illustrated in Fig. 2.

The major chemical constituents of seawater are consistent worldwide. The minor constituents, however, vary from site to site and with season, storms, and tidal cycles. These minor constituents include dissolved trace elements and dissolved gases. In addition, seawater contains dissolved organic materials and living microscopic organisms. Frequently, the minor

chemical constituents of seawater, together with the organic materials and living organisms, are the rate-controlling factor in the corrosion of structural metals and alloys.

Because of its variability, seawater is not easily simulated in the laboratory for corrosion-testing purposes. Stored seawater is notorious for exhibiting behavior as a corrosive medium that is different from that of the water mass from which it was taken. This is due in part to the fact that the minor constituents, including the living organisms and their dissolved organic nutrients, are in delicate balance in the natural environment. This balance begins to change as soon as a seawater sample is isolated from the parent water mass, and these changes often have a large effect on the types of corrosion experienced and the corrosion rate.

Variations in the chemistry of open ocean seawater tend to take place slowly (over time periods of 3 to 6 months) and over horizontal and vertical distances that are large in comparison to the dimensions of most marine structures. Such gradual changes may produce an equally gradual change in the corrosion rate of structural materials with season and location. However, they are unlikely to produce sharp changes in either corrosion mechanism or rate. Such gradual

changes are relatively easy to measure and monitor.

On the other hand, changes that take place over periods of hours to days and over distances of centimeters to meters can occur as the result of point inputs of various chemical pollutants or the attachment of micro- and macroscopic marine plants and animals to the surface of a structure. The chemical changes produced by the attachment of biological fouling organisms take place directly at the metal/water interface where the corrosion occurs, not in the bulk water. This means that the chemical environment in which the corrosion reactions occur in the presence of a micro- or macrofouling film may bear little resemblance to that of the bulk water.

It is these types of effects, which can be produced quickly and can lead to sharp chemical gradients over short distances, that often result in the onset of localized corrosion. Crevice Corrosion, beginning under the base of an isolated barnacle on stainless steel, is an example of this type of influence. Whether the fouling film is composed of microscopic bacteria or large sedentary fouling organisms is often less important than whether the film provides complete or spotty coverage of the metal surface. Almost invariably, a spotty film, or one that forms in discrete colonies of organisms with bare metal in between, will be more likely to induce structurally significant corrosion than a film that produces a continuous and homogeneous layer.

The general properties of ocean water and their effects on corrosion are discussed in the next section. The major and minor features, including the effects of variability, pollutants, and fouling organisms, are covered.

Consistency and the Major Ions

The concentrations of the major constituents of full-strength seawater are shown in Table 1. Major constituents are considered to be those that have concentrations greater than approximately 0.001 g/kg of seawater and are not greatly affected by biological processes. The behavior of these major ions and molecules is said to be conservative, because their concentrations bear a relatively constant ratio to

Fig. 1 Effect of NaCl concentration on the corrosion rate of iron in aerated room-temperature solutions. Data are compiled from several investigations. Source: Ref 1

Fig. 2 Zones of corrosion for steel piling in seawater, and relative loss of metal thickness in each zone. Source: Ref 2

each other over a wide range of dilutions. Although most of the known elements can be found dissolved in seawater, the ions and molecules listed in Table 1 account for over 99% of the total dissolved solids. Moreover, the conservative nature of these major ions means that all of their concentrations can be calculated if the concentration of any one of them, or the total salt content (salinity) of the water, is measured.

Salinity and Chlorinity. The most commonly measured property of seawater is its salinity. Salinity, S , in parts per thousand (ppt or ‰), historically has been defined as the total weight in grams of inorganic salts in 1 kg of seawater when all bromides and iodides are replaced by an equivalent quantity of chlorides and all carbonates are replaced by an equivalent quantity of oxides. Salinity is usually determined by measuring either the chlorinity or the electrical conductivity of the seawater. Chlorinity, Cl , is defined as the mass in grams of silver required to precipitate the halogens in 0.3285234 kg of seawater. This is nearly equal to the mass of chloride in the seawater sample. Chlorinity is related to salinity by:

$$S = 1.80655 \text{ } Cl \quad (\text{Eq } 1)$$

where S and Cl are measured in parts per thousand.

If pure water is the only substance added to or removed from seawater, the concentration of any ion, χ , from Table 1, at a salinity other than 35‰ can be calculated from the following relationship:

$$[\chi] \text{ at salinity } S = [\chi] \text{ at } 35\text{‰ salinity} \times S/35\text{‰} \quad (\text{Eq } 2)$$

where the brackets denote concentration, and S is again given in parts per thousand. For example, using Eq 2 and Table 1, the concentration of sodium ion in seawater of 20‰ salinity is:

$$\begin{aligned} [Na^+] \text{ at } 20\text{‰} &= (0.468 \text{ mol/kg of seawater}) \\ &\times 20\text{‰}/35\text{‰} \\ &= 0.2667 \text{ mol } Na^+/\text{kg of} \\ &\text{seawater} \end{aligned}$$

Table 1 Concentrations of the most abundant ions and molecules in seawater of 35‰ salinity

Density of seawater: 1.023 g/cm³ at 25 °C (75 °F)

Ion or molecule	Concentration	
	m mol/kg of seawater	g/kg of seawater
Na ⁺	468.5	10.77
K ⁺	10.21	0.399
Mg ²⁺	53.08	1.290
Ca ²⁺	10.28	0.412
Sr ²⁺	0.09	0.008
Cl ⁻	545.9	19.354
Br ⁻	0.84	0.067
F ⁻	0.07	0.0013
HCO ₃ ⁻	2.30	0.140
SO ₄ ²⁻	28.23	2.712
B(OH) ₃	0.416	0.0257

Source: Ref 3

This relationship may be less accurate at very low salinities (<10‰ for Ca²⁺ and HCO₃⁻ and <5‰ for the other major ions). The relationship may also lose accuracy in grossly polluted seawater. In this case, the concentration of the ion of interest must be known in both seawater and in the solution being added.

The only processes that affect the concentrations of the major ions over seasonal and shorter time periods are evaporation, precipitation, and river discharge. Because water is the only substance added to or removed from seawater by the first two of these processes, they affect the absolute concentrations of each ion but have no effect on the concentration ratios.

Effect of River Discharge. In contrast, river discharge does add constituents other than pure water. Therefore, the conservative behavior of the major ions may not hold in the low-salinity regions near river outlets. To a first approximation, river water is a 0.4 millimolar (m mol/L) solution of calcium bicarbonate as shown in Table 2 (Ref 4). At a salinity of 10‰, the calcium concentration calculated using Eq 2 and Table 1, but ignoring the river input, will be 10% too low. The error for bicarbonate ion will be even larger. Errors in concentrations of the other major ions, calculated by ignoring the river input, however, will be much less because of their relatively high concentrations in seawater compared to those in river water.

Salinity Variations. The total salt content of open ocean seawater varies from 32 to 36‰. It can rise above that range in the tropics or in enclosed waterways, such as the Red Sea, where evaporation exceeds freshwater input. It will be lower than that range in estuaries and bays, where there is appreciable dilution from river input. Salinity variations in the surface waters of the Pacific Ocean are shown in Fig. 3 (Ref 5). The data for these figures, as well as the surface water data for other variables to follow, were taken from the *Russian Atlas of the Pacific Ocean* (Ref 6). Many additional sources of information on the chemical properties of seawater are available. See, for example, the recent book by Pilson and the references therein (Ref 7).

Table 2 Concentrations of the most abundant ions and molecules in average river water

Ion or molecule	Concentration	
	m moles/L of river water	mg/L of river water
Na ⁺	0.274	6.3
K ⁺	0.059	2.3
Mg ²⁺	0.171	4.1
Ca ²⁺	0.375	15.0
Cl ⁻	0.220	7.8
HCO ₃ ⁻	0.958	58.4
SO ₄ ²⁻	0.117	11.2
NO ₃ ⁻	0.016	1.0
Fe ²⁺	0.012	0.67
Si(OH) ₄	0.218	20.9

Source: Ref 4

Salinity variations with depth at given locations in the Atlantic and Pacific Oceans are shown in Fig. 4. The locations from which these and other data on variations with depth were taken are illustrated in Fig. 5. It should be noted that the open ocean salinity variations with horizontal location and depth are quite small.

Effect of Salinity on Corrosion. The main effects of salinity on corrosion result from its influence on the conductivity of the water and from the influence of chloride ions on the breakdown of passive films. Specific conductance varies with temperature and chlorinity, as indicated in Table 3 (Ref 8). The high conductivity of seawater means that the resistance of the electrolyte plays a minor role in determining the rate of corrosion reactions and that surface area relations play a major role.

Two examples will serve to illustrate this point. First, galvanic corrosion in freshwater systems tends to be localized near the two-metal junction by the high resistivity of the electrolyte. In seawater, however, anodes and cathodes that are tens of meters apart can operate; therefore, the galvanic corrosion is much more spread out and is less intense at the junction. In the second example, a large area of cathodic metal, such as stainless steel, will produce more severe galvanic attack on an anodic metal in seawater than in freshwater, because high conductivity allows the entire area of stainless steel to participate in the reaction. Similarly, pitting corrosion tends to be more intense in seawater, because large areas of boldly exposed cathode surface are available to support the relatively small anodic areas at which pitting takes place.

The second effect of salinity on corrosion in seawater is related to the role of chloride ions in the breakdown of passivity on active-passive metals such as stainless steels and aluminum alloys. The higher the salinity of the water, the more rapidly chloride ions succeed in penetrating the passive film and initiating pitting and crevice corrosion at localized sites on the metal surface.

The open ocean salinity changes shown in Fig. 3 and 4 have very little effect on the processes of galvanic, pitting, and crevice corrosion. The much larger salinity changes found in coastal and brackish waters can have a substantial effect on both the susceptibility to and the intensity of localized corrosion. These coastal salinity changes have undoubtedly contributed to the variability in reported pitting and crevice corrosion rates with season and location or with time at a given location. For alloys that corrode uniformly, variations in corrosion rate due to salinity changes are small compared to those caused by changes in oxygen concentration and temperature.

Temperature. When all other factors are held constant, an increase in temperature increases the corrosivity of seawater. If the dissolved oxygen concentration is held constant, the corrosion rate of low-carbon steel in seawater will approximately double for each 30 °C (55 °F) increase in temperature.

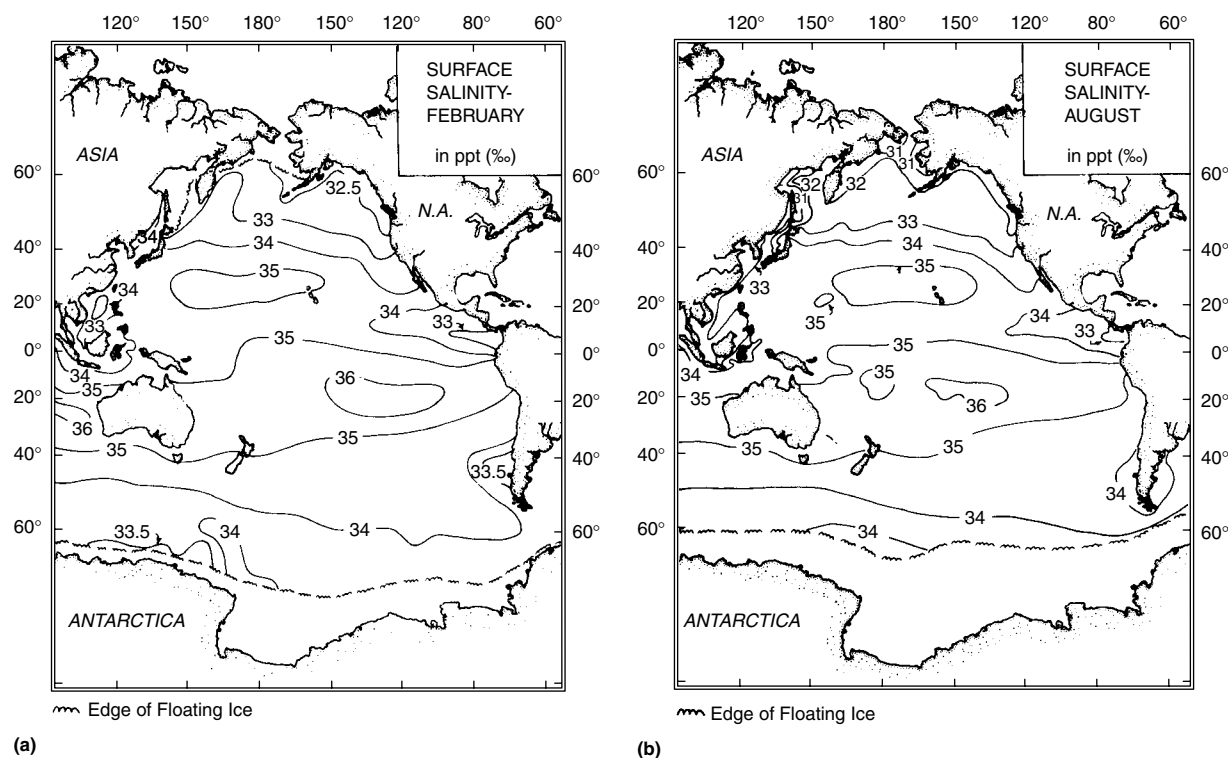

Fig. 3 Pacific Ocean surface salinity (‰) for (a) February and (b) August. Source: Ref 5

Open ocean temperature variations are shown for surface waters in Fig. 6 and, as a function of depth, in Fig. 7. From these data alone, one would expect corrosion rates in tropical surface waters to be approximately twice those in the polar regions or in deep water. Corrosion rates are usually higher in warm surface waters than in cold deep waters, as illustrated in Fig. 8 and 9 (Ref 9, 10), but the picture is not nearly as simple as temperature alone would indicate. For surface waters, the saturation level of dissolved oxygen increases as the temperature decreases, and the effects of dissolved oxygen on the corrosion rate are often stronger than those of temperature. Short-term local temperature fluctuations and the effects of biofouling and scaling films must also be considered.

The historical database for seawater immersion corrosion of carbon steels and low-alloy steels taken at a variety of sites has recently been analyzed, and a model for general corrosion has been proposed (Ref 11). Results from the modeling effort have revealed (Ref 11, 12) that for fully aerated seawater, the general trend is for increasing corrosion rates with average water temperature, as shown in Fig. 10. There is some indication that the temperature at the time of initial immersion may be more important than subsequent seasonal temperature fluctuations (Ref 11, 12).

Data for the temperature and salinity variations with depth at the four coastal locations in Fig. 5 are shown in Fig. 11 to 14. The

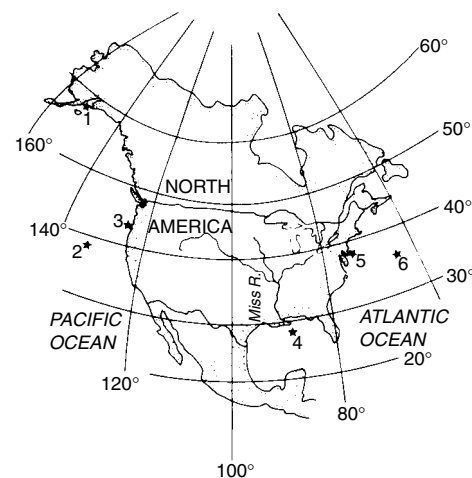

Fig. 4 Comparison of salinity-depth profiles for open ocean sites 2 and 6 (see Fig. 5 for site locations). Source: Ref 5

temperature and salinity profiles for Cook Inlet (station 1) and for the Oregon coast (station 3) given in Fig. 11(a,b) and 12(a,b), respectively, show only small differences with depth and season. No reliable data are available for the

Station number	Location	Chart coordinates
1	Cook Inlet	58° 57' N 152° 59' W
2	Northeast Pacific	38° 21' N 133° 38' W
3	West coast, U.S.	44° 39' N 124° 39' W
4	Gulf of Mexico	28° 12' N 88° 26' W
5	East coast, U.S.	39° 20' N 73° 40' W
6	Northwest Atlantic	36° 44' N 64° 28' W

Fig. 5 Station positions for Fig. 4, 7, 11-14, 17, and 29. Source: Ref 5

winter months at the Cook Inlet station. The differences shown here are inconsequential with regard to corrosion.

Larger differences are shown for the Gulf of Mexico (station 4) and the New Jersey coast (station 5) in Fig. 13 and 14. The temperature differences with depth and season shown for these two locations are large enough to influence both corrosion rate and calcareous deposition. The salinity changes shown will have little

influence. The seasonal differences in the surface waters of the Gulf of Mexico disappear at greater depths, while those off the New Jersey coast persist all the way to the bottom.

Variability of the Minor Ions

This section considers how the variability of the minor constituents of seawater affects

corrosion. Variabilities in seawater properties with horizontal location and depth are presented for the dissolved gases, oxygen and carbon dioxide, and for various pH values. Each of these properties has a range over which it typically varies in the marine environment. The effect on corrosion of each property as it changes within this range is considered.

Dissolved Oxygen. Many of the minor constituents that are important to corrosion processes are dissolved gases such as carbon dioxide and oxygen. Their concentrations are not conservative (that is, constant), because they are influenced by air-sea exchange as well as by biochemical processes. The concentration of dissolved oxygen in surface waters is usually within a few percent of the equilibrium saturation value with atmospheric oxygen at a given temperature. The solubility of oxygen in seawater varies inversely with both temperature and salinity, but the effect of temperature is greater. If the absolute temperature *T* (°K) and salinity *S* (‰) are known, the solubility of oxygen can be calculated from the relationship:

$$\ln [O_2] = A_1 + A_2 \left(\frac{100}{T} \right) + A_3 \ln \left(\frac{T}{100} \right) + A_4 \left(\frac{T}{100} \right) + S \left[B_1 + B_2 \left(\frac{T}{100} \right) + B_3 \left(\frac{T}{100} \right)^2 \right]$$

(Eq 3)

where oxygen concentration is given in milliliters per liter (mL/L), and salinity S is in parts per thousand (‰). The constants A_1 through B_3 are given in Table 4 (Ref 7, 13). Table 5 lists the equilibrium oxygen saturation levels in milliliters per liter as a function of temperature and salinity calculated from Eq 3 and Table 4.

Generally, the surface waters of the ocean are in equilibrium with the oxygen in the atmosphere at a specific temperature. Two sets of conditions, however, can lead to these waters becoming substantially supersaturated with oxygen. The first of these conditions is oxygen production due to photosynthesis by microscopic marine plants.

Fig. 7 Comparison of temperature-depth profiles for open ocean sites 2 and 6 (see Fig. 5 for site locations). Source: Ref 5

Fig. 8 Corrosion rates of carbon steels and wrought iron in the Atlantic and Pacific Oceans at various depths. Source: Ref 9, 10

During high growth periods, intense photosynthesis can produce concentrations as high as 200% saturation for periods of up to a few weeks. Such oxygen levels are most often found in near-shore regions as a transient phenomenon.

The second condition that may cause oxygen supersaturation is the entrainment of air bubbles due to wave action. This factor usually will not cause greater than approximately 10% supersaturation, because vigorous wave action also promotes re-equilibration with the atmosphere.

Oxygen Variability. The distribution of dissolved oxygen in the surface waters of the Pacific Ocean is shown in Fig. 15(a) for the months of January through March and in Fig. 15(b) for July through September. Comparison with Fig. 6 reveals that the highest concentrations of oxygen coincide with the lowest temperatures; this agrees with the oxygen solubility data given in Table 5.

Surface waters are either saturated or supersaturated with oxygen at atmospheric conditions. In contrast, deep waters tend to be isolated from the atmosphere above them. Waters currently in the deep ocean are thought to have formed thousands of years ago in cold, polar regions. At the time of formation, these waters were cold, dense, and rich in oxygen. Due to their high density, they sank down and spread out in horizontal layers throughout the deep portions of the world ocean. Thus, the oxygen concentrations of deep ocean waters today have no direct relation to oxygen in the atmosphere above them. Deep waters are usually high in dissolved oxygen according to the location of their origin. Waters at intermediate depths are often undersaturated due to consumption of oxygen during the

biochemical oxidation of organic matter. Figure 16 shows horizontal maps of dissolved oxygen concentration in the Pacific Ocean at depths of 500 and 1000 m (1640 and 3280 ft). The level of oxygen is generally lower at these depths, especially in the northeastern Pacific.

This decrease in oxygen concentration with depth is shown more clearly in Fig. 17. The oxygen profiles for the open Atlantic and Pacific stations both go through a minimum at intermediate depths and increase again at great depths. In the Atlantic Ocean, the surface oxygen concentrations are usually lower, and the oxygen minimum is not as intense as in the Pacific. In addition, the oxygen concentrations in the deep Atlantic are higher than those in the deep Pacific, and they can be even higher than those in the Atlantic surface waters for reasons given previously.

Figure 18 shows the depth of the dissolved oxygen minimum in the Pacific (solid contours) and the concentration of oxygen at that depth (dotted contours). The depth of the oxygen minimum ranges from 400 m (1310 ft) in the equatorial eastern Pacific to over 2400 m (7875 ft) in the central south Pacific. The concentration of oxygen at the depth of the minimum ranges from 0.01 to 0.40 mg·atm/L (1 mg·atm/L = 12.2 mL/L = 16 ppm at 25 °C, or 75 °F). Oxygen profiles with depth for the four coastal stations were shown in Fig. 11 to 14.

Effect of Oxygen on Corrosion. The corrosion rate of active metals (for example, iron and steel) in aerated electrolytes such as seawater at constant temperature is a direct linear function of the dissolved oxygen concentration, as shown in Fig. 19. When oxygen and temperature vary

Fig. 9 Corrosion rates of low-carbon steels in the Atlantic and Pacific Oceans at various depths. Source: Ref 9, 10

together, as they do in the marine environment, the oxygen effect tends to predominate. This trend is illustrated by data for the corrosion rate of steel at various depths in the Pacific Ocean in

Fig. 20. The corrosion rate decreases with dissolved oxygen down to the oxygen minimum, then increases again with oxygen at greater depths, despite a continuing decrease in

Fig. 10 Average corrosion loss versus average seawater temperature for copper-bearing steels, showing data points and trend lines. Solid points are considered by author of Ref 11 to have a strong correlation to aerated open sea conditions. Open points have a weaker correlation. Source: Ref 11. temperature. The corrosion rates of nickel and nickel-copper alloys are somewhat less affected by oxygen concentration, as shown in Fig. 21. The effect of oxygen on copper alloys depends on the flow velocity. Figure 22 shows that there is very little effect of oxygen on copper alloys exposed in quiet open ocean water. At a flow velocity of 1.8 m/s (6 ft/s), however, increasing oxygen has a marked accelerating effect (Fig. 23) on the corrosion rate.

In contrast, the effect of oxygen on the corrosion rates of active-passive metals, such as aluminum alloys, stainless steels, and other corrosion-resistant alloys, can be quite variable (Fig. 24). For such alloy systems, high oxygen concentrations tend to promote healing of the passive film and thus retard initiation of pitting corrosion. On the other hand, high oxygen favors a vigorous cathodic reaction and tends to increase the rate of pit and crevice propagation after initiation.

For all alloy systems, the conditions most conducive to corrosion are those in which differences in dissolved oxygen are allowed to develop between two regions of the wetted metal surface. This can lead to an oxygen concentration cell, with potential differences as large as 0.5 V. The portion of metal surface on which the oxygen concentration is lowest becomes the anode and is subject to localized corrosion. Differences in dissolved oxygen concentration of this type are unlikely to occur over short distances within the water itself. Instead, they are usually caused by localized deposits or structural design factors that create oxygen-shielded regions on the metal surface.

These effects also can lead to pitting corrosion of active metals such as carbon and low-alloy steels. The average uniform corrosion rates of carbon and low-alloy steels in a wide variety of marine environments are found to range from 0.050 to 0.125 mm/yr (2 to 5 mils/yr), slowly decreasing with time of exposure. Data from the Panama Canal zone showed that, although the average penetration rate was 0.068 mm/yr (2.7 mils/yr), the penetration by pitting was some five to eight times higher (Fig. 25).

Differences in dissolved oxygen from point to point along the metal surface caused by spotty biofouling films can contribute to the pitting rate.

Fig. 13 Variation of (a) temperature, (b) salinity, and (c) oxygen concentration with depth and season in the Gulf of Mexico (station 4, Fig. 5). Source: Ref 5

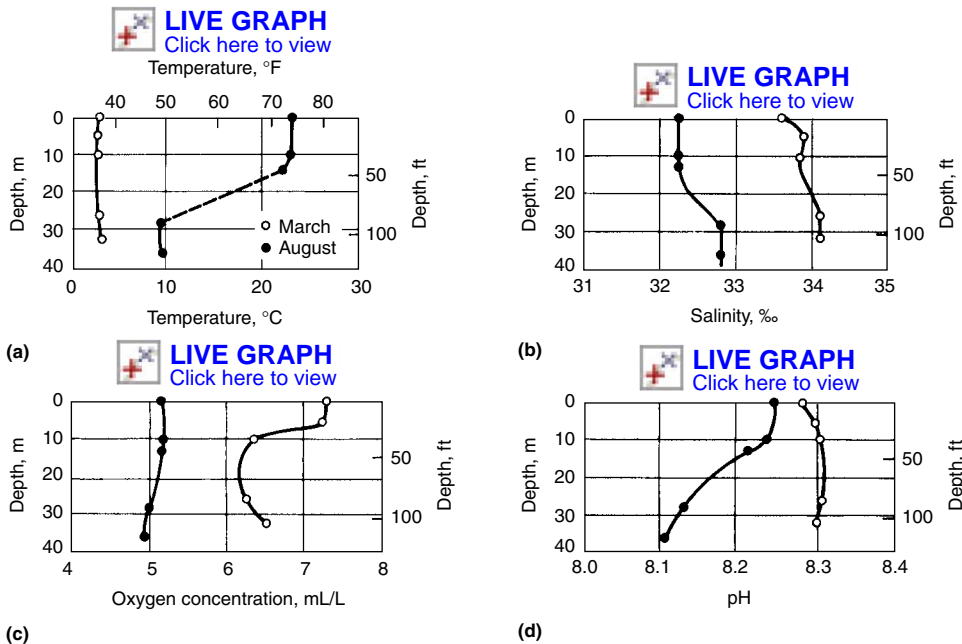

Fig. 14 Variation of (a) temperature, (b) salinity, (c) dissolved oxygen, and (d) pH with depth and season off the New Jersey and Delaware coasts (station 5, Fig. 5). Source: Ref 5

In contrast to the effects of a spotty film, complete coverage of the surface by hard-shelled, sedentary fouling organisms can lead to a marked decrease in the overall corrosion rate by acting as a diffusion barrier against dissolved oxygen reaching the metal surface. In the case of aluminum and stainless alloys, point-to-point differences in oxygen concentration can lead to both pitting and crevice corrosion.

Dissolved Carbon Dioxide and pH. The concentration of carbon dioxide is less affected by air-sea interchange than the concentration of dissolved oxygen, because the carbon dioxide system in seawater is buffered by the presence of bicarbonate and carbonate ions. Carbon dioxide is a weak acid and undergoes two ionizations in aqueous solutions (Ref 7):

Surface seawater usually has a pH value greater than 8 because of the combined effects of air-sea exchange and photosynthesis. At this pH, 93% of the total inorganic carbon is present as HCO_3^- , 6% as CO_3^{2-} , and 1% as CO_2 . Bicarbonate ion accounts for at least 85% of the total inorganic carbon under all naturally-occurring conditions. However, the relative concentrations of CO_2 and CO_3^{2-} vary greatly depending on pH. The CO_3^{2-} concentration is relatively high in surface waters, and surface waters are nearly always supersaturated with respect to the calcium carbonate phases calcite and aragonite. This supersaturation favors deposition of calcareous scales on metal surfaces undergoing cathodic protection, as is discussed later.

Relationship Among CO_2 , Oxygen, and pH. The concentrations of carbon dioxide and oxygen are closely coupled and related to the pH of seawater through the processes of photosynthesis and biochemical oxidation, as represented in the following general reaction (Ref 7):

where CH_2O represents a typical carbohydrate molecule. During decomposition of organic material in seawater, Eq 6 proceeds from left to right, dissolved oxygen is consumed, and CO_2 is

produced. Production of CO_2 , in turn, makes the water more acidic (that is, lower pH) and decreases the saturation state with respect to carbonates.

Variability of pH. The pH of the Pacific surface waters ranges from 8.1 to 8.3, and its general distribution for the months of January to March is shown in Fig. 26. Distributions of pH at depths

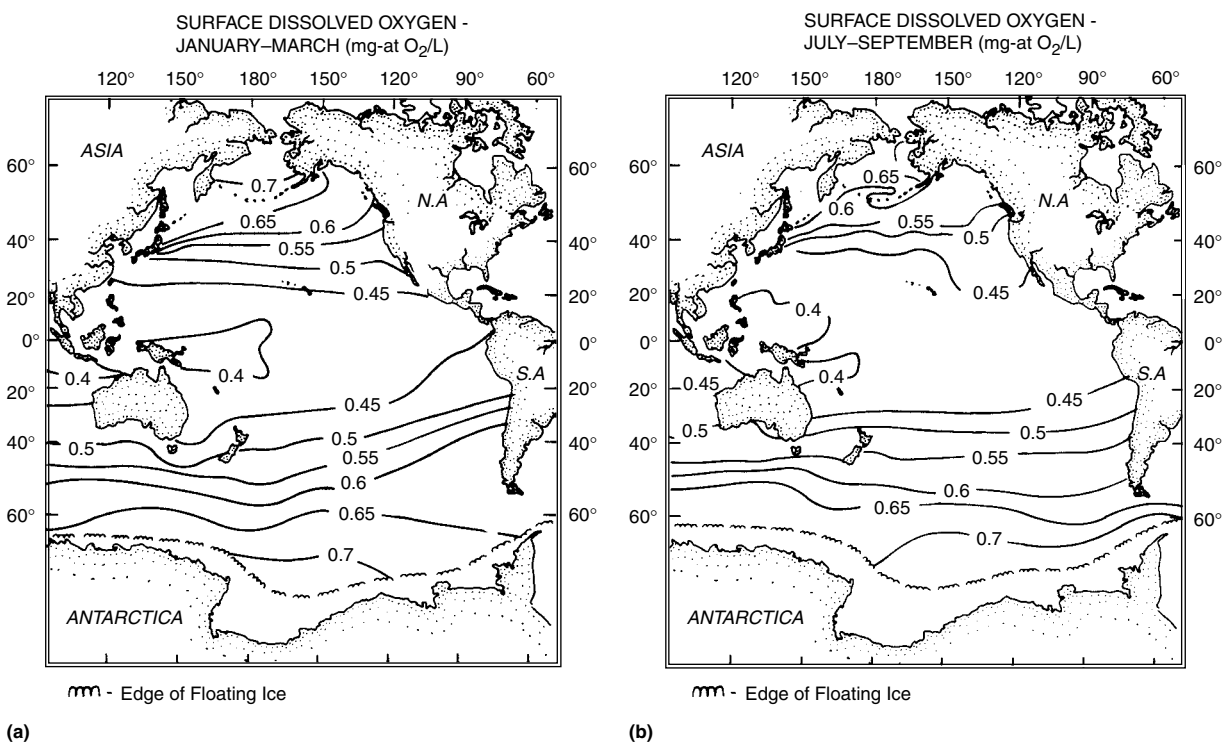

Fig. 15 Pacific Ocean surface dissolved oxygen (mg · atm/L) for (a) January through March and (b) July through September. (1 mg · atm/L = 12.2 mL/L). Source: Ref 5

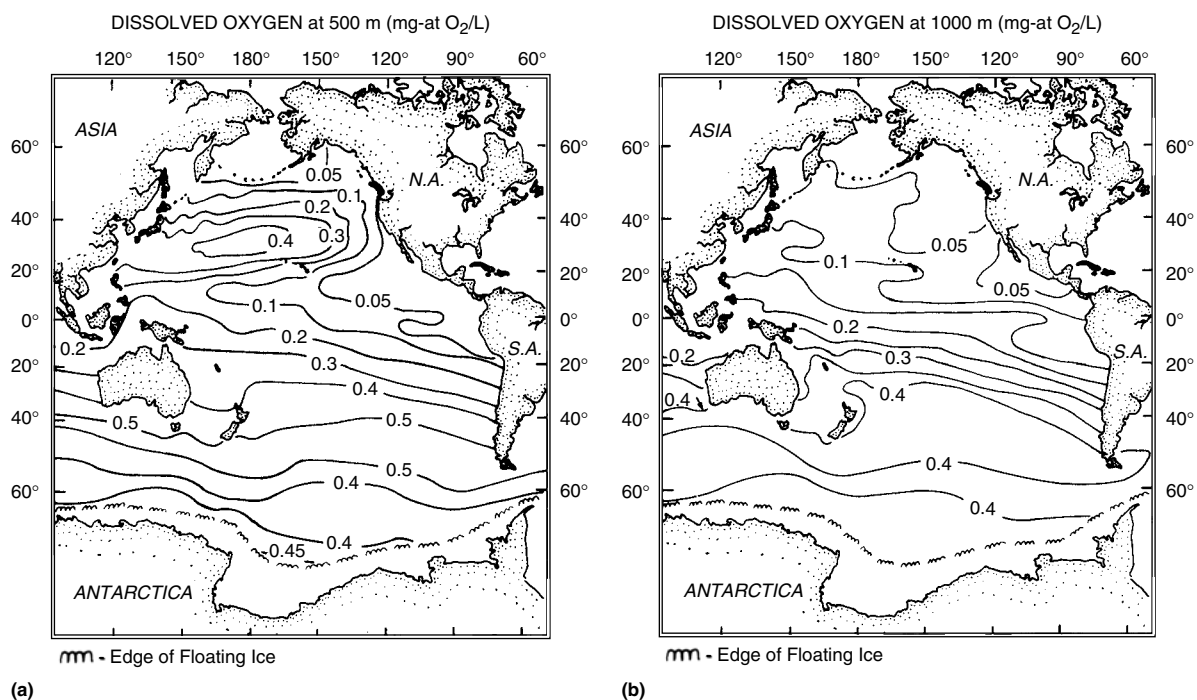

Fig. 16 Pacific Ocean dissolved oxygen (mg · atm/L) at depths of (a) 500 m (1640 ft) and (b) 1000 m (3280 ft). (1 mg · atm/L = 12.2 mL/L). Source: Ref 5

of 500 and 1000 m (1640 and 3280 ft) are shown in Fig. 27 and 28, respectively. In comparing these to the dissolved oxygen distributions at the same depths (Fig. 15 and 16), it should be noted that the trends for the two variables are similar. For example, at a depth of 500 m (1640 ft), the region of maximum dissolved oxygen, centered on 180° longitude between 20 and 40° north latitude in Fig. 16(a), is reproduced closely for pH in Fig. 27.

Fig. 17 Comparison of dissolved oxygen-depth profiles for open ocean stations 2 and 6 (see Fig. 5). Source: Ref 5

Profiles of pH with depth for the two open ocean locations are shown in Fig. 29. A comparison of the corresponding pH and oxygen profiles from Fig. 17 and 29 reveals the closely coupled nature of their relationship through the carbon dioxide system. The oxygen and pH minima are reached at the same depth for a given location, as was predicted. The deep North Pacific water is from 0.15 to 0.40 pH units more acidic than that in the North Atlantic, primarily because of the increased oxidation of organic matter in the North Pacific.

Profiles of pH for the coastal waters off Oregon and New Jersey were shown in Fig. 12 and 14, respectively. The close correlation between the shapes of the oxygen and pH profiles in both winter and summer for the Oregon data in Fig. 12 is particularly striking. Upon close examination, the oxygen and pH profiles in Fig. 14 do not appear to be closely related in the manner seen earlier. In March, the water column is well mixed down to the bottom, and the changes with depth of all four variables are small. In August, however, the dissolved oxygen profile is nearly independent of depth, while the pH and temperature profiles show substantial changes. Based on salinity and temperature, the oxygen saturation levels during August are approximately 5.2 mL/L in the surface waters and 6.5 mL/L in the deep water. The oxygen profile for August shows that the surface waters are nearly saturated, while in the deep waters, biological activity has used up enough oxygen and produced enough CO₂ to decrease the pH—but not enough to produce a strong oxygen

minimum. This indicates the danger inherent in assuming that a pH minimum will always correspond to a similar minimum in oxygen. The two profiles may not correspond closely in shape when the biological demand for oxygen is not sufficiently intense to produce a strong oxygen minimum or when there is a strong temperature gradient.

Effects of pH on Corrosion and Calcareous Deposition. The pH of open ocean seawater ranges from approximately 7.5 to 8.3. Changes within this range have no direct effect on the corrosion of most structural metals and alloys. The one exception to this general statement is the effect of pH on aluminum alloys. A decrease in pH from the surface water value of 8.2 to a deep water value of 7.5 to 7.7 causes a marked acceleration in the initiation of both pitting and crevice corrosion (Ref 14). This effect accounts for the reported increase in corrosion of aluminum alloys in the deep ocean (Ref 15).

Although variations in seawater pH have little direct effect on corrosion of alloys other than aluminum, they do have an indirect effect through their influence on calcareous deposition.

The surface waters of most of the world's oceans are 200 to 500% supersaturated with respect to the calcium carbonate species calcite and aragonite (Ref 7). Thus, precipitation of carbonate-type scales will occur readily on any solid surface where there is an elevated pH in the water at the interface.

Scale precipitation is most likely to occur in the elevated-pH regime adjacent to cathodically protected surfaces, where OH⁻ ions are produced by the cathodic reactions involving reduction of dissolved oxygen (Ref 16) and breakdown of water. The predominant calcareous specie precipitated in warm surface waters is aragonite and, at interface pH values above 9.3

(as experienced during cathodic protection) (Ref 16), brucite (Mg(OH)₂).

For many years, the marine cathodic protection industry has relied on the buildup of calcareous scales to make cathodic protection more economical. The scale deposit on cathodically protected steel is normally composed of an initial magnesium-rich inner layer, followed by a thicker outer layer of aragonite (Ref 17). The higher the pH at the water/metal interface, the more brucite is favored and the lower the calcium-magnesium ratio of the deposit will be (Ref 16, 17). A lower calcium-magnesium ratio, in turn, makes the scale less dense and less protective. Thus, a high level of cathodic protection

applied in the early stages of immersion, as is sometimes done to accelerate scale buildup, can be counterproductive in terms of scale quality if it is maintained continuously at the same high level. It has been found that the most protective deposits are formed by the so-called rapid polarization approach, in which a high initial current is applied to encourage rapid surface coverage by the magnesium-rich phase, brucite, followed by a lower current to form the more protective aragonite (Ref 18, 19). This has led to the development of dual anodes composed of a thin outer layer of magnesium over an inner core of aluminum (Ref 19, 20).

In deep waters, where the temperature and pH are both lower than at the surface, calcareous deposits do not form spontaneously under ambient conditions, and it has often been difficult to form deposits even under cathodic protection conditions. This is partly because the deep waters—below 300 m (985 ft) in the Atlantic

and 200 m (655 ft) in the North Pacific—are undersaturated in carbonates as a result of low pH and high pressure (Ref 7). At the low temperatures of the deep water, calcite is the predominant calcium carbonate phase. At first, this would seem to be beneficial, because calcite forms a dense, protective film. However, calcite formation is strongly inhibited by the free magnesium ions that are abundant in seawater (Ref 16). Recent tests on deep water deployments found that while brucite and aragonite deposits could be formed in deep water, they were less

protective than those formed in surface waters, and the rapid polarization technique was not effective (Ref 21, 22).

Effect of Pollutants

The ratios of the major ions are not affected by pollution of the water as long as the salinity remains above 5 to 10‰. The relations between the major, conservative ions will hold constant, except perhaps in a confined waterway with poor tidal flushing in which a pollutant containing a large concentration of one of the major ions is introduced in quantities approaching that of the waterway itself.

In contrast, the concentrations of the minor constituents of seawater may be radically changed by pollution. This is an important fact, because it is usually the minor ions and dissolved gases that determine the corrosion rate. Concentrations of heavy metals; nutrients such as nitrates and phosphates; dissolved organics; and dissolved gases such as oxygen, carbon dioxide, and hydrogen sulfide are particularly sensitive to pollution.

Effects Related to Dissolved Oxygen. Pollutants containing organic material usually increase the utilization of dissolved oxygen in the water. As the organics become oxidized, oxygen concentrations fall, carbon dioxide concentrations rise, and the water becomes more acidic. If the pH does not fall below 4, these conditions often result in a decrease in the corrosivity of the water toward carbon and low-alloy steels. During the first half of this century, for example, the upper Delaware estuary in the Chester-Philadelphia, PA, area was sufficiently polluted that the yearly mean dissolved oxygen in the Delaware River was nearly zero. Consequently, the corrosion rates of industrial steel structures in that waterway were very low during that period. As political pressure directed toward cleaning up the river mounted during the 1950s and 1960s, the yearly mean dissolved oxygen began to recover. By the mid-1970s, the oxygen concentrations had increased enough that “lace-paper” conditions were being noted on sheet steel and H-pilings in the area. In contrast, the corrosion rate for steel structures in low-oxygen (or even anoxic) waters and sediments can increase if certain types of bacteria are active. For active-passive metals such as aluminum and stainless steels, which undergo localized corrosion at pits and crevices, a decrease in the bulk

Fig. 25 Corrosion of carbon steel and wrought iron continuously immersed in seawater. Average penetration rate was 0.068 mm/yr (2.7 mils/yr) for steel; that of wrought iron was 0.061 mm/yr (2.4 mils/yr). Source: Ref 9

water oxygen concentration can produce either an increase or decrease in the corrosion rate. Localized oxygen and other chemical concentration cells along the metal surface can be more important for these alloys than the bulk water values.

Sulfides. Hydrogen sulfide and various sulfates are frequent components of organic pollutants. Sulfates themselves are not particularly detrimental except that they can be reduced to sulfides by the action of sulfate-reducing bacteria. The effects of these bacteria are considered later. Hydrogen sulfide may reach levels of 50 ppm or higher in severely polluted estuarine or harbor waters. Bottom muds in harbors and salt marshes rich in decomposing organic matter may also have high sulfide concentrations.

Penetration by pitting corrosion of low-carbon steel panels in the polluted seawater of the San Diego harbor was several times higher than the uniform penetration rates usually experienced (Ref 9) (Table 6). Similarly, the corrosion rate of several copper alloys used in condenser service was 3 to 10 times higher in polluted than in clean seawater (Ref 9) (Table 7), and as little as 4 ppm of hydrogen sulfide seriously increased the corrosion rate of copper alloys, as shown in Table 8 (Ref 9).

Sulfide films are well known to form on copper alloys in polluted waters. These films can be very harmful. Under most conditions, the sulfide film is itself cathodic to the bare copper alloy surface. This makes the film effective in accelerating pitting corrosion at any break in the film, and the effects on corrosion are known to persist long after the polluted water has been removed. For this reason, it is important to remove sulfide films from copper alloys, even when the source of

pollution has been eliminated (Ref 23). The sulfide film will continue to accelerate pitting corrosion as long as it remains on the metal surface, even in clean water. It is usually recommended that the first exposure of copper alloys be in clean, rather than sulfide-polluted, seawater whenever possible. Experience has shown that if sulfide films are allowed to form before other corrosion product films on the copper alloys of a marine condenser or piping system, they can be very difficult to remove. Moreover, even after cleaning, traces of the sulfide film are likely to plague that system throughout its service life (Ref 23).

Heavy Metals. Nominally unpolluted seawater contains nearly every known element, most of them in very small concentrations. For example, the copper concentration in clean seawater is approximately 0.2 ppb (Ref 24). This does not normally cause corrosion problems for any of the common marine structural alloys (Ref 23). At elevated copper concentrations, however, aluminum alloys can suffer accelerated corrosion. The copper concentration in the water can be elevated by copper-containing pollutants, by leaching from copper-base antifouling paints, or by corrosion of copper alloys (Ref 23).

Acceleration of aluminum corrosion by copper corrosion products has often been observed in seawater piping systems having copper alloy pumps, even when the aluminum piping is not in direct electrical contact with the copper alloy (Ref 23). In freshwater, copper concentrations as low as 0.05 ppm have been found to accelerate aluminum corrosion. In seawater, the threshold concentration below which copper contamination has no effect seems to be approximately 0.03 ppm, as shown in Fig. 30 (Ref 24). Copper accumulates on the aluminum surface by

electrochemical deposition and provides an efficient cathode; this depolarizes the aluminum and can lead to the initiation of pitting corrosion (Ref 23, 24).

A similar effect has sometimes been observed for iron and steel corrosion products generated upstream of aluminum components in desalination plants. However, the effect of iron contamination is not as strong or as consistent as that of copper.

Influence of Biological Organisms

Seawater is a biologically active medium that contains a large number of microscopic and macroscopic organisms. Many of these organisms are commonly observed in association with solid surfaces in seawater, where they form biofouling films. Because the influence of both micro- and macrofouling organisms on corrosion has been dealt with in detail in the article "Microbiologically Influenced Corrosion" in *ASM Handbook*, Volume 13A, 2003, only a brief description is given here. Immersion of any solid surface in seawater initiates a continuous and dynamic process, beginning with adsorption of nonliving, dissolved organic material and continuing through the formation of bacterial and algal slime films and the settlement and growth of various macroscopic plants and animals (Ref 25–27). This process, by which the surfaces of all structural materials immersed in seawater become colonized, adds to the variability of the marine environment in which corrosion occurs. The rate of biofilm formation is a function of nutrient concentrations, velocity of water flow, and temperature (Ref 28).

Bacterial Films. The process of colonization begins immediately upon immersion, with the adsorption of a nonliving organic conditioning film. This conditioning film is nearly complete within the first 2 h of immersion, at which time the initially colonizing bacteria begin to attach in substantial numbers. The microbial, or primary, slime film develops over the first two weeks of immersion in most natural seawaters, providing highly variable degrees of coverage of the metal surface (Ref 27, 29). Biofilms are typically composed of pillar- and mushroom-shaped cell

clusters separated by water channels that allow nutrients in and waste products out (Ref 30–32).

Microorganisms in the biofilm change the chemistry at the metal/liquid interface in a number of ways that have an important bearing on corrosion. As the biofilm grows, the bacteria in the film produce a number of by-products. Among these are organic acids (Ref 33), hydrogen sulfide (Ref 34, 35), and protein-rich polymeric materials commonly called slime. Formation of biofilms can also change the pH at the metal surface (Ref 36–38).

Moreover, the development of a microbial biofilm, an example of which is shown in Fig. 31, results in a heterogeneous distribution of microorganisms both parallel and perpendicular to the metal surface (Ref 39). This creates a heterogeneous distribution of the chemistry from point to point along the metal surface. The result is not only a different chemistry at the metal surface from that of the bulk water but also a highly variable chemistry along the surface on a scale of tens to hundreds of micrometers (Ref 40, 41). Such chemical concentration cells increase the likelihood that the corrosive attack will be localized rather than uniformly distributed.

Two chemical species, oxygen and hydrogen, that are often implicated (or even rate-controlling) in corrosion are also important in the metabolism of the bacteria. A given bacterial slime film can be either a source or a sink for oxygen or hydrogen. Coupled together with the heterogeneous nature of the chemistry and distribution of biofilms, this means that they are capable of inducing oxygen and other chemical concentration cells (Ref 40, 41).

Under anaerobic (no oxygen) conditions, such as those found in marshy coastal areas and many sea bottom sediments, in which all the dissolved oxygen in the mud is used in the decay of organic matter, the corrosion rate of steel is expected to be very low. Under these conditions, however, sulfate-reducing bacteria use hydrogen produced at the metal surface in reducing sulfates from decaying organic material to sulfides, including H_2S . The sulfides combine with iron from the steel to produce an iron sulfide (FeS) film, which is itself corrosive. The bacteria thus transform a benign environment into an aggressive one in which steel corrodes quite rapidly in the form of pitting (Ref 42–45).

Even under open ocean conditions at air saturation, the presence of a heterogeneous bacterial slime film can result in anaerobic conditions at selected sites along the metal surface (Ref 40, 41, 46). This creates anaerobic micro-niches where sulfate-reducing bacteria can flourish, encouraging localized attack.

In all of these cases, the biofilm is able to make substantial changes to the chemistry of the electrolyte and its distribution at the water/metal interface. In doing this, microbes facilitate electrochemical reactions not predicted by thermodynamic analysis of the bulk water chemistry (Ref 47). Another example of this lies in the ability of biofilms formed from river water,

estuarine, and coastal seawater environments to introduce manganese reduction (in addition to that of dissolved oxygen) as a cathodic reaction

supporting corrosion (Ref 48–50). Manganese redox cycling, in which microbes in marine biofilms reoxidize manganese species reduced at

Fig. 30 Effect of adding Cu^{2+} ion to seawater on the time to pit initiation for aluminum alloy 5052 and 99.99% Al. Solid points represent conditions under which pitting started; open points indicate conditions under which no pitting occurred. Source: Ref 24

Fig. 31 Laser confocal microscope image of the variability in distribution and types of microorganisms in a 2-week-old biofilm grown on a stainless steel substratum in Lower Delaware Bay coastal seawater. The chemistry at the metal surface within a microcolony, as shown at location "A," will be quite different from that in either the bulk seawater or at location "B." Source: Ref 39

the cathode of a corrosion cell, is thought to be responsible for the ennoblement of passive alloys, acceleration of crevice corrosion of stainless steels (Ref 51, 52), and acceleration of galvanic corrosion for copper, steel, and aluminum alloys coupled to stainless steel cathodes (Ref 53). The heterogeneity of the biological community within microbial biofilms also can produce anaerobic areas rich in biogenic sulfides only a few tenths of a millimeter away from other areas having nearly air-saturated concentrations of oxygen or partially deaerated areas rich in biologically produced manganese compounds (Ref 41). The potential difference between such areas can be as high as 500 mV (Ref 39). In comparison, differential aeration cells are quite weak. Even for an oxygen concentration differential of 10^4 between the aerated and deaerated areas, the potential difference is only approximately 60 mV. Thus, the type of attack as well as the corrosion rate may depend more on the details of the electrolyte chemistry at the interface than on the ambient bulk seawater chemistry. Additional details about many aspects of biological corrosion can be found in the article "Microbiologically Influenced Corrosion" in *ASM Handbook*, Volume 13A, 2003.

Macrofouling Films. Within the first 2 or 3 days of immersion, the solid surface, already having acquired both conditioning and bacterial films, begins to be colonized by the larvae of macrofouling organisms. A heavy encrustation of these organisms can have a number of undesirable effects on marine structures. Both weight and hydrodynamic drag on the structure will be increased by the fouling layer. Interference with the functioning of moving parts may also occur.

In terms of corrosion, the effects of the macrofouling layer are similar to those of microfouling. If the macrofoulers form a continuous layer, they may decrease the availability of dissolved oxygen at the metal/water interface and can reduce the corrosion rate. If the layer is discontinuous, they may induce oxygen or chemical concentration cells, leading to various types of localized corrosion. Fouling films may also break down protective paint coatings by a combination of chemical and mechanical action.

Effect of Flow Velocity

An increase in velocity of flow is generally regarded as causing an increase in average corrosion rates (Ref 54). The historical database of information on velocity effects on marine corrosion has recently been reviewed (Ref 55). Average seawater velocities below 0.25 m/s (0.82 ft/s) (nominally laminar flow) increased the instantaneous corrosion rate of steel proportional to the square root of velocity. At higher flow velocities in the turbulent flow range, the instantaneous corrosion rate increased as the square of the velocity. The gradual buildup with

time of both corrosion product scales and biofilms on the metal surface provides a shielding effect against the influence of velocity. Thus, the effects of velocity are most important in the early stages of immersion. Removal of such films by erosion or abrasive action from ice or suspended sediments is expected to restore the effect of flow velocity. It was also concluded that average wave action had an effect roughly equivalent to a flow velocity of 0.1 to 0.15 m/s (0.3 to 0.5 ft/s) as long as the wave action did not remove corrosion product or biological films (Ref 55).

Corrosion in Marine Atmospheres

Richard B. Griffin, Texas A&M University

THE ANNUAL COST OF CORROSION has been estimated to be 3.1% of the gross national product for the United States. According to a recent study, the 1998 cost for the United States was \$276 billion. See the article "Direct Costs of Corrosion in the United States" in *Corrosion: Fundamentals, Testing, and Protection*, Volume 13A of *ASM Handbook*, 2003. A substantial part of the total is due to atmospheric corrosion (Ref 1). Buildings, automobiles, bridges, storage tanks, ships, and other items that must be repaired, coated, or replaced represent some of the costs attributed to atmospheric corrosion in the economy.

Truly, worldwide interest exists in this topic. Several factors contribute to marine-atmospheric corrosion, with the local environment being the single most important factor. The most aggressive condition is a warm tropical coastal location with prevailing onshore winds that carry both Cl^- and SO_4^{2-} to the site. Moving inland (decreasing Cl^-) and decreasing SO_4^{2-} concentrations will decrease the extent of marine-atmospheric corrosion.

Both nickel alloys and stainless steels have very good-to-excellent resistance to marine-atmospheric corrosion. Changing the composition of plain carbon steel to that of weathering steel will increase the resistance to marine-atmospheric corrosion. Coating plain carbon steels can improve resistance to marine-atmospheric corrosion.

Modeling has become a very important method of assessing a local environment without having to develop long-term corrosion data. However, the results must be carefully used, and long-term data should be developed. Results from the models provide a very useful means of making comparisons. For steels, in particular, the results are acceptable.

The International Standards Organization (ISO) has made a significant contribution to the study of atmospheric corrosion. Standards have been developed and applied to sites located around the globe. The standards are in the process of being updated, and the reader should check for the latest revisions. In addition, ASTM International is active in establishing standards for atmospheric corrosion.

Typically, atmospheric corrosion is divided into the categories listed in Table 1, which

includes the corrosion rates for low-carbon steel at a variety of locations with different atmospheric conditions (Ref 2). The International Standards Organization has established a set of corrosion standards that enable the corrosivity of a location to be described in terms of the time of wetness, sulfur dioxide, and chloride levels (Ref 3, 4). The marine or marine-industrial environments are generally considered to be the most aggressive. Important variables associated with atmospheric corrosion in marine atmospheres are chloride and sulfur dioxide content, location, alloy content, and exposure time. These are examined in this article, and the ISO CORRAG program is discussed. In addition, corrosion comparisons of metal alloys are included.

Important Variables

A number of factors, such as moisture, temperature, winds, airborne contaminants, alloy content, location, and biological organisms, contribute to atmospheric corrosion.

Moisture. For corrosion to occur by an electrochemical process, an electrolyte must be present. An electrolyte is a solution that will allow a current to pass through it by the diffusion of anions (negatively charged ions) and cations (positively charged ions). Water that contains

ions is a very good electrolyte. Therefore, the amount and availability of moisture present is an important factor in atmospheric corrosion. For ferrous materials beyond a certain critical relative humidity (RH), there will be an acceleration of the atmospheric corrosion rate. The critical RH is 60% for iron in an atmosphere free of sulfur dioxide (Fig. 1a). For magnesium under similar conditions, 90% RH is critical (Fig. 1b) (Ref 5). The critical RH is not a constant value; it depends on the hygroscopicity (tendency to absorb moisture) of the corrosion products and the contaminants. The type of moisture is significant. For example, rain may help wash contaminants from surfaces, while dew and fog allow surfaces to become wet without the washing action of the rain.

One of the measures of moisture is time of wetness (TOW). As Fig. 2 shows, corrosion rate increases as TOW increases (Ref 6). In addition, Fig. 2 illustrates the importance of a contaminant; when sulfur dioxide (SO_2) levels increase, a corresponding increase in the overall corrosion rate occurs. The ISO 9223 quantifies the TOW (τ); details are discussed later in this article (Ref 3). However, the severity of the marine environment is related to the salt content of the atmosphere that contacts the material surface, which is usually more corrosive than rainfall without Cl^- .

Table 1 Types of atmospheres and corrosion rates of low-carbon steel

Test duration: 2 years

Atmosphere	Location	Corrosion rate	
		mm/yr	mils/yr
Marine	Point Reyes, CA	0.5	19.71
Severe	25 m (80 ft) lot, Kure Beach, NC	0.53	21.00
Industrial	Brazos River, TX	0.093	3.67
Mild	250 m (800 ft) lot, Kure Beach, NC	0.146	5.73
Rural	Esquimalt, BC, Canada	0.013	0.53
Industrial	East Chicago	0.084	3.32
Marine	Bayonne, NJ	0.077	3.05
Urban	Pittsburgh, PA	0.03	1.20
Suburban (semi-industrial)	Middletown, OH	0.029	1.13
Rural	State College, PA	0.023	0.90
Marine	Esquimalt, BC, Canada	0.013	0.53
Desert	Phoenix, AZ	0.0046	0.18

Source: Ref 2

For acid rain conditions, there appears to be no significant increase in corrosion rate. A study conducted in Sweden from October to November 1976 for carbon steels showed an increase in corrosion rates with increasing SO_2 ; however, the incidences were relatively infrequent. The study also showed that the corrosion

rates measured for a longer time do not seem to be influenced by the incidences of acid rain (Ref 6). Similar results were obtained in a British study of the atmospheric corrosion of zinc (Ref 7).

Airborne Contaminants. After TOW, the second most important factor in atmospheric corrosion is the contaminants found in the air. These can be natural or manmade, such as airborne moisture carrying salt from the sea, or SO_2 put into the atmosphere by coal-burning utility plants. The importance of the atmospheric SO_2 level on the corrosion rate of zinc has been seen (Fig. 2). As the parts per million of SO_2 increase, the weight loss of zinc increases. Other important contaminants are chlorides (Cl^-), carbon dioxide (CO_2), nitrogen oxides (NO_x), and hard dust particles (for example, sand or minerals).

Chlorides. There is a direct relationship between atmospheric salt content and measured corrosion rates. The amount of sea salts measured off the coast of Nigeria illustrates this relationship between salinity and corrosion rate (Ref 8). This is shown in Fig. 3, in which salinity of $10 \text{ gm/m}^2/\text{d}$ results in a corrosion rate of less than $0.1 \text{ g/dm}^2/\text{mo}$, while a salinity of $1000 \text{ gm/m}^2/\text{d}$ results in a corrosion rate of almost $10 \text{ g/dm}^2/\text{mo}$. At the LaQue Center for Corrosion Technology (Wrightsville Beach, NC) test site at Kure Beach, NC, a similar effect has been observed for carbon steel. The corrosion rate at the site 25 m (80 ft) from the mean tide line (this site is now called the oceanfront lot) was 1.19 mm/yr (47 mils/yr), while at the 250 m (800 ft) location (this site is now called the near-ocean lot), the corrosion rate for the same material was 0.04 mm/yr (1.6 mils/yr).

Chlorides are contained within droplets formed from seawater that have been entrained in the air. The droplets will evaporate and leave a residue of salt on the surface. From a corrosion standpoint, the droplets bring both water and chloride to a surface. The distance that droplets are carried inland will depend on the size of the droplets and the air currents.

The average atmospheric chloride levels collected in rainwater for the United States are shown in Fig. 4 (Ref 6). The highest levels occur along the coast of the Atlantic Ocean, Pacific Ocean, and the Gulf of Mexico. The maximum corrosion rate is related to the maximum chloride in the atmosphere. This will be related to the distance inland, the height above sea level, and the prevailing winds. The chlorides of calcium and magnesium are hygroscopic and have a tendency to form liquid films on metal surfaces, which increases TOW.

Sulfur Dioxide. The presence of SO_2 in the atmosphere lowers the critical RH while increasing the thickness of the electrolyte film and increasing the aggressiveness of the environment. For carbon steel, the effect of SO_2 levels from three Norwegian test sites is shown in Fig. 5. These data and Fig. 2 illustrate that as SO_2 concentrations are increased, the corrosion rate increases. A summary of Scandinavian data for carbon steel and zinc showed the following relationships between corrosion rate and SO_2 concentrations:

$$r_{\text{St}} = 5.28[\text{SO}_2] + 176.6 \quad (\text{Eq 1a})$$

$$r_{\text{Zn}} = 0.22[\text{SO}_2] + 6 \quad (\text{Eq 1b})$$

where r is the atmospheric corrosion rate in $\text{g/m}^2/\text{yr}$, and $[\text{SO}_2]$ represents the concentration of SO_2 in $\mu\text{g/m}^3$ (Ref 9). Similar types of relationships have been shown for other alloy systems and locations, as is described later in this article.

Sulfur dioxide is very acidic and will dissolve in water and form sulfuric acid in the presence of oxygen:

Fig. 3 Atmospheric corrosion of mild steel as a function of salinity at various sites in Nigeria. Source: Ref 8

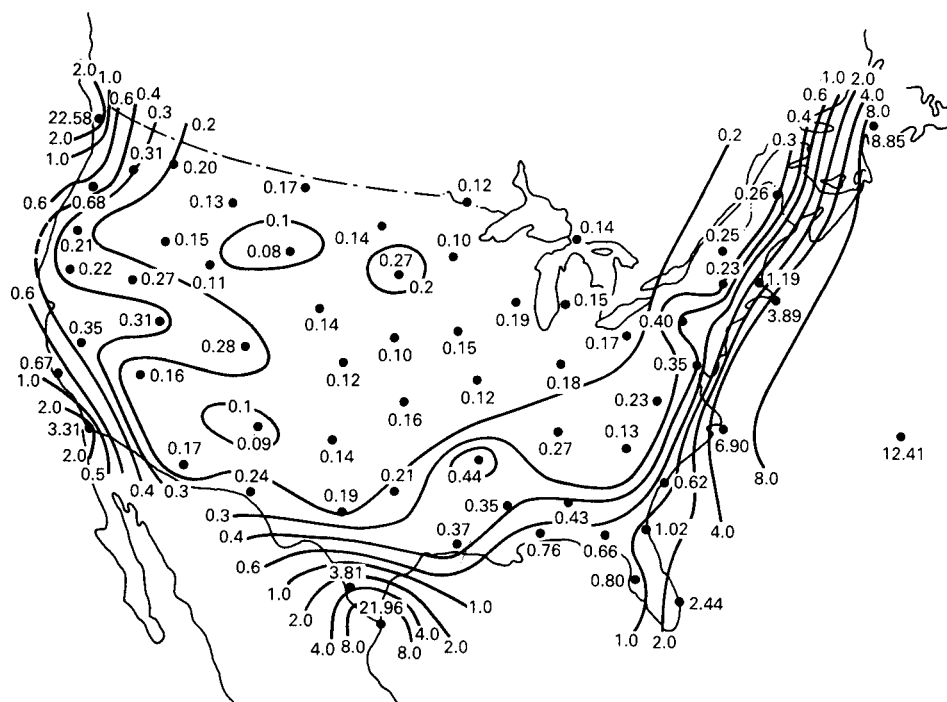

Fig. 4 Average chloride concentration (mg/L) in rainwater in the United States. Source: Ref 6

In marine environments, SO_2 often appears as a result of the burning of sulfur-containing fuels that are not properly controlled.

Carbon Dioxide. The opinion of the majority of investigators is that carbon dioxide (CO_2) has an effect on the corrosion of metals. Carbon dioxide in the presence of water forms carbonic acid (Eq 3 and 4). A $\text{pH} < 7$ may be obtained with atmospheric CO_2 in equilibrium with pure water (Ref 10):

Carbonates are found in corrosion products on a number of metals. The presence of CO_2 is important for zinc to be able to form a protective carbonate layer. Carbon dioxide does not have nearly the same level of significance in atmospheric corrosion as SO_2 and Cl^- .

Location. The site where materials are located is a very important variable in atmospheric corrosion. The distance from the sea and the height above sea level are both significant.

Distance from the Sea. Figure 3 shows the effect of moving inland along the coast of Nigeria from the 45, 365, and 1190 m (50, 400, and 1300 yd) sites at Lagos. From studies done on Barbados, the effect of distance is confirmed by the map of the island shown in Fig. 6 (Ref 11). This represents one of the worst conditions: tropical beach, on-shore winds, and facing a large, uninterrupted stretch of ocean. Similarly, at a site in Aracaju, Brazil, low-carbon steel samples were tested at five sites from approxi-

Fig. 6 Estimates of marine-atmosphere corrosivity at various locations on the island of Barbados in the West Indies. Based on CLIMAT data. Source: Ref 11

mately 0.1 to almost 4 km (0.06 to 2.5 miles) from the sea. There was a rapid falloff in the corrosion rate as the testing sites were moved inland (Fig. 7). By approximately 1.5 km (0.9 miles) inland, the corrosion rate had reached a value that showed it was basically independent of the marine atmosphere (Ref 12). The formation of aerosol droplets as a function of wind and surf zones for the distance ~400 m to 600 m (440 to 660 yd) inland is characterized by an exponential expression and describes nicely the variation in corrosion rate (Ref 13).

Fig. 5 Effect of SO_2 concentration on the corrosion rate of carbon steel at three Norwegian sites. Source: Ref 9

Fig. 7 Corrosion rate of carbon steel as a function of distance from the sea at Aracaju, Brazil. Source: Ref 12

The height above sea level of specimens is also important. In Fig. 8(a) the corrosion rate of carbon steel specimens in the 25 m (80 ft) oceanfront lot at Kure Beach, NC, varied from approximately $360 \mu\text{m/yr}$ (14 mils/yr) at a height of 5 m (16.5 ft) to $600 \mu\text{m/yr}$ (24 mils/yr) at a height of approximately 8 m (26 ft). There is considerably less corrosion for the carbon steel at the Kure Beach, NC, 250 m (800 ft) near-ocean test site (Fig. 8b), where the corrosion rate for carbon steel varies from approximately $50 \mu\text{m/yr}$ (2 mils/yr) to a maximum of approximately $230 \mu\text{m/yr}$ (9 mils/yr). Here, the average chloride content is $100 \text{ mg/m}^2/\text{d}$, while at the ocean-front lot it is approximately $400 \text{ mg/m}^2/\text{d}$ (Ref 14).

In the splash zone (see Fig. 2 in the article "Corrosion in Seawater" in this Volume), the highest corrosion rate is slightly above mean high tide. This zone not only has high chloride content but also is alternately wet and dry. As the height above the sea increases, the corrosion rate decreases, because the specimen is not as wet as often.

Orientation. Another corrosive factor is the orientation of a material with respect to the earth's surface. Results for a 1 year exposure of iron specimens placed vertically and inclined at

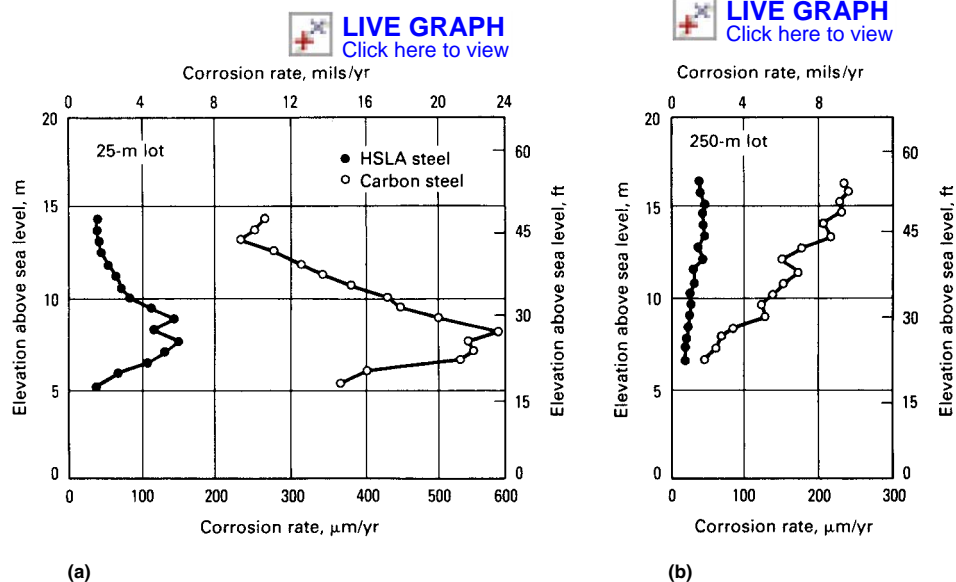

Fig. 8 Effect of elevation above sea level for carbon and high-strength, low-alloy (HSLA) steels at Kure Beach, NC. (a) 25 m (80 ft) lot. (b) 250 m (800 ft) lot. Source: Ref 14

an angle of 30° with respect to the ground are shown in Fig. 9 (Ref 14). The spread in the data is much greater for the Kure Beach 25 m (80 ft) test lot than for the 250 m (800 ft) test lot. In both cases, the vertical specimens showed a higher corrosion rate. This was attributed to the formation of a nonuniform, less protective oxide in the vertical position than in the 30° position. It is also possible that the 30° samples have the chloride deposits cleaned from their surfaces more easily than the vertical specimens. Ratios of the corrosion rate in the vertical position to that in the 30° position are given in Table 2 for five sites (Ref 14). In the vertical position, the corrosion rate is greater on the side facing the sea than on the side facing land. At the 25 m (80 ft) lot at Kure Beach, steel pipe specimens corroded at the rate of $850 \mu\text{m}/\text{yr}$ (33.5 mils/yr) facing the ocean, as compared to $50 \mu\text{m}/\text{yr}$ (2 mils/yr) facing away from the ocean over a 4.5 year period.

The corrosion rate was measured on the skyward and groundward side of specimens that are parallel to the earth's surface. Tests conducted at Kure Beach showed that the skyward side corroded at a greater rate after 3 months. However, after 6 months of testing, the rates were identical. Similarly, for an AZ31B magnesium alloy in a 30 day test, the skyward-facing specimens lost more material than the groundward-facing ones.

For corrosion tests performed on mild steel and low-alloy copper steel in Australia, the 1 year corrosion rates for sheltered and open exposures are shown in Fig. 10. The chloride content has a significant effect. For example, at $40 \text{ mg}/\text{m}^2/\text{d}$, the corrosion rate for the sheltered locations was approximately $38 \mu\text{m}/\text{yr}$ (1.5 mil/yr), while for the open exposure it was approximately $20 \mu\text{m}/\text{yr}$ (0.8 mil/yr). It is interesting to note that the alloys swapped positions when comparing open and sheltered sites (Ref 15).

Table 2 Comparison of atmospheric corrosion rates for specimens held vertically and inclined at 30° to the horizontal

Temperature affects the RH, TOW, and the kinetics of the corrosion process. For atmospheric corrosion, the presence of moisture as determined by TOW is probably the most important role of temperature. Figure 11 shows the effect of temperature on iron, zinc, and copper (Ref 5). Increasing temperature over the range of 20 to 40°C (70 to 100°F) while holding the chloride content ($16 \text{ mg}/\text{m}^3$) and RH (80%) constant results in three distinct patterns: corrosion rate increases for iron, decreases for zinc, and remains constant for copper.

The temperature of interest may not be the average daily temperature. It may be more important to know the dewpoint temperature or the surface temperature. From an atmospheric corrosion standpoint, minimizing the TOW reduces the corrosion rate.

Sunlight influences the degree of wetness and affects the performance of coatings and plastics. Sunlight may also stimulate photosensitive corrosion reactions on such metals as copper and steel. Ultraviolet (UV) light and photo-oxidation can cause embrittlement and surface cracks in polymers. This can be avoided by the addition of UV absorbers (for example, carbon black).

Wind. The direction and velocity of the wind affect the rate of accumulation of particles on

Fig. 9 Effect of specimen orientation on corrosion rates of iron specimens exposed vertically and at an angle of 30° to the horizontal. Results of one-year test at Kure Beach, NC. Source: Ref 14

Fig. 10 Corrosion rates of mild steel and low-alloy copper steel versus site mean level of airborne chloride. Source: Ref 15

Fig. 11 The effect of temperature on the corrosion rates of iron, zinc, and copper. Source: Ref 5

metal surfaces. Also, wind disperses the airborne contaminants and pollutants. Figure 6 shows that the corrosion rate zones widen from an ocean beach facing the prevailing wind. The effect caused by the chloride ions being carried inland is illustrated in Fig. 7, which shows an increased corrosion rate at 1 km (0.6 mile) inland. Stronger prevailing winds can carry the airborne contaminants even further inland. A marine site may be even more aggressive due to the prevailing winds bringing industrial pollutants, particularly SO_2 , to the marine site.

Time. For many materials, there is a decrease in the corrosion rate as time increases. This decrease is associated with the formation of protective corrosion layers. Figure 12 provides an example of this for low-carbon steel at eight sites in South Africa (Ref 16). An initial increase in the atmospheric corrosion rates occurs, followed by a slowing down of the corrosion rates as corrosion products form on the alloy surface. This is true only for sites C through G. For site A and B, the corrosion rate is sufficiently high to prevent the formation of a protective layer; therefore, a constant very high corrosion rate was maintained. The effect of marine-atmospheric corrosion on tensile strength is shown in Fig. 13 for low-carbon steel and three aluminum alloys. The initial rate of loss in ultimate tensile strength is highest, but as time continues, the rate of loss decreases except for the low-carbon steel at Kure Beach and Point Judith (Ref 17).

Starting Date. The initial variation in the corrosion rate may depend on when the tests were started. Figure 14 compares the measured weight losses for iron and zinc in tests started at two different dates (Ref 6). Over a 60 day test, the variation in corrosion rate for zinc is much larger than that for iron. Similarly, for iron specimens at the Kure Beach oceanfront lot (25 m, or 80 ft), there are variations of hundreds

Fig. 12 Change in corrosion rate as a function of time for eight South African sites. Source: Ref 16

Fig. 13 Loss in tensile strength as a function of time for (a) 1.6 mm ($1/16$ in.) low-carbon steel and (b) aluminum alloys of the same thickness at five test sites. Data in (b) are averages for aluminum alloys 1100, 3003, and 3004. Source: Ref 17

of micrometers per year in corrosion rates as measured on samples exposed vertically for 1 and 2 years each. This is shown in Fig. 15 for iron calibration specimens tested from 1949 through 1979 (Ref 14).

Site Variability. Large variations in atmospheric corrosion rate occur within a particular type of region. An example would be the corrosion behavior of steel and zinc in different tropical environments. Figure 16 shows the average penetration for steel in a 1 year test at tropical sites (Ref 18). For zinc under similar conditions, the average penetration varied from 31 to 11 μm (1.2 to 0.4 mils). As Fig. 13 shows, there is a wide variation in the loss of tensile strength between the four seacoast locations.

Temperature, tropical-marine sites, and inland sites are compared in Fig. 17 for zinc and copper. The zinc corrodes more rapidly at the tropical-marine site; however, the reverse is true at the inland site, where the corrosion rate at State College, PA, is higher than at Miraflores, Panama. Overall, the long-term (15 to 20 years) rates for copper are similar at both marine and inland sites (Ref 18).

A similar comparison for carbon and low-alloy steels (Fig. 18) illustrates that the tropical environment has a higher overall corrosion rate. Figure 18(a) compares the stabilized corrosion rate for carbon steel of 20 $\mu\text{m}/\text{yr}$ (0.8 mil/yr) at Cristobal, Panama, to 16 $\mu\text{m}/\text{yr}$ (0.63 mil/yr) at Kure Beach, NC, near-ocean lot (250 m, or 800 ft). Low-alloy steel exhibited a similar increased rate of corrosion, as shown in Fig. 18(b). The stabilized corrosion rate is the slope of the average penetration corrosion loss-time curve. The values are given next to the curves in Fig. 18 and 19. The same pattern is exhibited for carbon steel at inland sites (Fig. 18c) (Ref 18).

A comparison of 1, 2, and 4 year corrosion rates for aluminum, copper, zinc, and iron is given in Table 3 as part of the ISO CORRAG program. The five sites used were Kure Beach (KB, 250 m, or 800 ft, lot), Newark-Kearny (NK), Point Reyes (PR), Panama Canal Zone (PCZ), and Los Angeles (LA-USC). Plate- and helix-shaped specimens were used. Generally, the helix exhibited larger corrosion loss than the plate. Table 4 provides the environmental data for the five sites (Ref 19).

corrosion conditions classified as moderate and severe marine (Ref 20). Above 12 or 12.5 wt% Cr, the atmospheric corrosion becomes negligible; lower chromium levels result in a rapid increase in the corrosion rate. Table 5 provides compositions for 11 type 300- and 400-series stainless steels tested at the near-ocean lot

(250 m, or 800 ft), Kure Beach, NC, over a 15 year period (Ref 21). Table 6 lists the 15 year pit depths, the surface roughness (R_a) at 60 years, the average corrosion rate, and the 60 year mass change for the 10 austenitic (300-series) alloys listed in Table 5. The average pit depth varied, for a 15 year study, from 86 μm/yr (3.4 mils/yr)

for type 347 (UNS S34700) to 10 μm/yr (0.4 mils/yr) for type 310 (UNS S31000). (It is unlikely that the actual pitting rates would be linear with respect to time, but these data are as reported.) The mass loss during the 60 years of exposure is low, with a maximum of 0.07 g and a minimum of 0.01 g. The average corrosion rates

(a) Based on 8 year data. Source: Ref 22

were equal to or less than 0.03 µm/yr (0.001 mil/yr). From the data in Table 6, the alloys with the best resistance are type 309 (UNS S30900), 317 (UNS S31700), 316 (UNS S31600), and 310 (Ref 21). For austenitic stainless steel alloys, it is important to avoid sensitization, resulting in intergranular attack, and the buildup of chloride ions on 304L and 316L under a load, which potentially may lead to stress-corrosion cracking.

Another category of steels that is of interest for marine-atmospheric corrosion applications are weathering steels. Four weathering steels and their compositions are listed in Table 7 (Ref 22). The predicted 50 year corrosion penetration results are given in Table 8 for three environments. Each material has four orientations. The highest average predicted penetrations (2523 µm, or 99.3 mils) are for the carbon steel, which has the lowest copper alloy content, in the moderate-marine environment. In contrast, the predicted average value for ASTM A242, under the same conditions, is approximately one-tenth of the carbon steel value (268 µm, or 10.5 mils) (Ref 22). Using the ISO corrosivity recommendations, the moderate-marine site would be a C₄ or C₅ site (Ref 3). Figure 22 shows a comparison of the aforementioned weathering steels at marine, rural, mountaintop, and rooftop sites. Of those four sites, the marine environment exhibits the highest corrosion (Ref 23). Additional sources of information are available in the ASTM standards listed in Table 9.

Another important group of materials for resisting atmospheric corrosion is coated materials. In Table 10, the corrosion losses for

(a) Also 3.6 wt% Nb

galvanized and 55% Al-Zn-coated steel specimens exposed for 21 years are listed (Ref 24). Only specimens with less than 5% rust were used for the corrosion-loss calculations. The maximum loss was 19.8 μm (0.8 mil) or less than 1 $\mu\text{m}/\text{yr}$ (0.04 mil/yr) over a 21 year period at the worst site, Kure Beach, and approximately 20% of that value for the AZ55 coating at Point Reyes. The details on the coating specimens are in Table 11.

Nickel alloys are considered to have excellent atmospheric corrosion resistance. Six nickel

alloys were tested at five sites: Kure Beach, NC; Kearny, NJ; Point Reyes, CA; State College, PA; and Panama Canal Zone, Panama. The compositions of the alloys are given in Table 12; they range from Ni 200 (UNS N02200) with 99.5% Ni to alloy 800 (UNS N08800) with 32.5% Ni and 67.5% alloying elements (Ref 25). The results after 20 years of corrosion are shown in Table 13, which refers to Table 10 for the test sites. All six of the alloys corroded less than 0.001 mm/yr (0.04 mil/yr). The deepest pit was found on the N02200 alloy, and it was only 0.046 mm (1.8 mil) deep (an average of the four deepest pits). With increasing alloy content and avoiding the seacoast environment, the pitting was <0.01 mm (0.4 mil) in depth. The mechanical properties, after 20 years of exposure, are tabulated in Table 14 (Ref 25).

Table 15 provides an excellent tabulation of general corrosion, pitting, and loss of tensile strength for a wide variety of metals and alloys, including aluminum, copper, carbon steels, coated steels, and stainless steels (Ref 18).

Exposure Time. One of the difficulties with atmospheric-corrosion testing is the length of time required for the tests. For steels, while a reasonable estimate of long-term corrosion performance may be made from short-term data, these estimates must be used very cautiously, because the short-term results may not be representative. It is best to have long-term data available. Fortunately, there are considerable long-term data available for a number of alloy steels (Ref 26). Table 15 provides data for a tropical seacoast site, Cristobal, Panama, and includes up to 16 years of data for many different alloys, including steels.

A power-law relationship is often used for describing long-term corrosion data (Ref 27):

$$M = aT^n \quad (\text{Eq } 5)$$

where M is the mass loss per unit area, T is the exposure time, n is the mass loss exponent (Table 17) or slope, and a is the mass loss during the first year.

Table 16 provides data from test sites in Europe, Central America, and the United States where exposure times ranged from 12 to 30 years for steel, zinc, and copper (Ref 28). The table includes experimental data and corrosion rates predicted using ISO 9224 and the power-law representation. The data in Table 16 show better agreement between predicted and measured rates for steel and zinc than for copper. The range of n -values used in the calculations for different ISO corrosivities is shown in Table 17 (Ref 28).

Modeling of Atmospheric Corrosion—ISO CORRAG Program

The ISO organization has developed an atmospheric-corrosion classification scheme.

Source: Ref 25

The outline for this is shown in Fig. 23 for ISO categories 9223 to 9226 (Ref 29). The ISO scheme considers TOW, SO₂, and Cl⁻ content. Table 18 defines the ISO parameters, where “P” represents Cl⁻, “S” represents SO₂, and τ represents the TOW (Ref 30). The ISO classifications for “P” and “S” are given in Table 19, and TOW is shown in Table 20 (Ref 30). The description of the five ISO 9223 categories C₁ through C₅ is given in Table 21 for carbon steel, zinc, copper, and aluminum (Ref 30). As an example, for corrosion rates of steel < 1.3 μm/yr (0.05 mil/yr), the corrosivity is categorized as very low, while for corrosion rates between 80 and 200 μm/yr (3.2 and 7.9 mils/yr), the corrosivity is given as very high. Table 22 provides a list of sites from around the world that have corrosion rates listed, and for 27 of the sites, their corrosivity category as determined from ISO 9223 is included (Ref 31).

Considerable effort has been made through ISO to determine 1 year corrosion rates for steel, zinc, copper, and aluminum. Equations modeling this behavior are given as follows. Equations 6 through 9 are based on data taken from 1 year of exposure and may be used only for classification purposes (Ref 30).

The dose-response functions are as follows for carbon steel (C_{St}, N = 119, R² = 0.87), zinc (C_{Zn}, N = 116, R² = 0.78), copper (C_{Cu}, N = 114, R² = 0.81), and aluminum (C_{Al}, N = 108, R² = 0.61):

$$C_{St} = 0.085SO_2^{0.56} TOW^{0.53} \exp\{f_{St}\} + 0.24Cl^{0.47} TOW^{0.25} \exp\{0.049T\}$$

$$f_{St}(T) = 0.098(T - 10) \text{ when } T \leq 10^\circ C$$

$$f_{St}(T) = -0.087(T - 10) \text{ when } T > 10^\circ C$$

(Eq 6)

$$C_{Zn} = 0.0053SO_2^{0.43} TOW^{0.53} \exp\{f_{Zn}\} + 0.00071Cl^{0.68} TOW^{0.30} \exp\{0.11T\}$$

$$f_{Zn}(T) = 0 \text{ when } T \leq 10^\circ C$$

$$f_{Zn}(T) = -0.032(T - 10) \text{ when } T > 10^\circ C$$

(Eq 7)

$$C_{Cu} = 0.00013SO_2^{0.55} TOW^{0.84} \exp\{f_{Cu}\} + 0.0024Cl^{0.31} TOW^{0.57} \exp\{0.030T\}$$

$$f_{Cu}(T) = 0.047(T - 10) \text{ when } T \leq 10^\circ C$$

$$f_{Cu}(T) = -0.029(T - 10) \text{ when } T > 10^\circ C$$

(Eq 8)

$$C_{Al} = 0.00068SO_2^{0.87} TOW^{0.38} \exp\{f_{Al}\} + 0.00098Cl^{0.49} TOW^{0.38} \exp\{0.057T\}$$

$$f_{Al}(T) = 0 \text{ when } T \leq 10^\circ C$$

$$f_{Al}(T) = -0.031(T - 10) \text{ when } T > 10^\circ C$$

(Eq 9)

Table 17 Predictions for long-term atmospheric corrosion of low-carbon steel, zinc, and copperThe range of the exponent n in Eq 5 for each type of atmosphere and ISO corrosivity category (Ref 3) are shown.

Material	Rural-urban atmospheres (without marine component)		Industrial atmospheres (without marine component)		Marine atmospheres	
	ISO corrosivity category	Range of n in Eq 5	ISO corrosivity category	Range of n in Eq 5	ISO corrosivity category	Range of n in Eq 5
Low-carbon steel	C ₁ –C ₃	0.3–0.7	C ₄ –C ₅	0.3–0.7	C ₁ –C ₅	0.6–0.9
Zinc	C ₁ –C ₃	0.8–1.0	C ₄ –C ₅	0.9–1.0	C ₁ –C ₅	0.7–0.9
Copper	C ₁ –C ₄	0.5–0.9	C ₅	0.6–0.8	C ₁ –C ₅	0.4–0.6

$f_M(T)$ is the function for the particular metal, N is the number of tests, and R^2 is the statistical term estimating goodness of fit; $R^2 = 1$ is a perfect fit.

Table 23 provides the description of the symbols and the intervals used in the previous equations. The equations include the TOW, SO_2 , and the Cl^- deposition rate. The results are

reasonable, and a comparison between the predicted and the observed values is shown in Fig. 24 (Ref 30).

Additionally, linear regression relationships are used to describe atmospheric corrosion. Equation 10 is an example (Ref 29):

$$\ln(r_{\text{corr}}) = b_0 + b_1[\text{SO}_2] + b_2\ln[\text{Cl}] + b_3\ln[\text{TOW}] \quad (\text{Eq 10})$$

where r_{corr} is the corrosion loss per year ($\mu\text{m}/\text{yr}$), $[\text{SO}_2]$ is the yearly average of concentration of SO_2 ($\mu\text{g}/\text{m}^3$), $[\text{Cl}]$ is the yearly average of deposition rate of chloride ($\mu\text{g}/\text{m}^2 \cdot \text{d}$), TOW is the percentage of hours per year when the RH is greater than 80% at a temperature greater than 0 °C (%), and b_0 , b_1 , b_2 , and b_3 are coefficients given in Table 24.

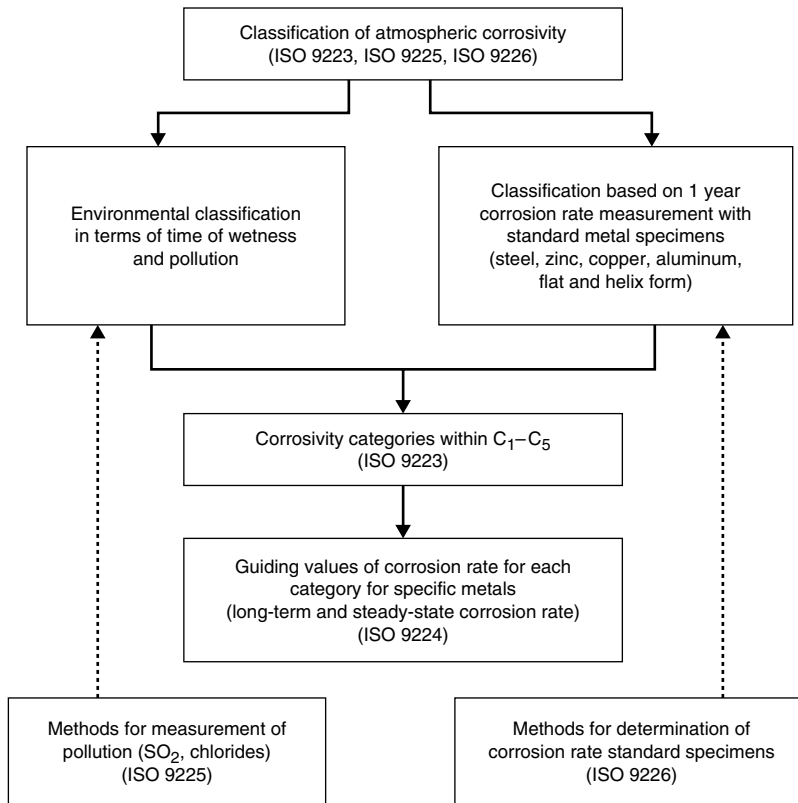

Fig. 23 Scheme for classification of atmospheric-corrosivity approach in ISO 9223 to 9226. Source: Ref 29

Table 18 Estimated corrosivity category for unalloyed carbon steel for time of wetness (TOW) category τ_3 , τ_4 , and τ_5 and different SO_2 (P_0 to P_3) and Cl (S_0 to S_3) categories

TOW chloride classification	τ_3			τ_4			τ_5		
	S_0 - S_1	S_2	S_3	S_0 - S_1	S_2	S_3	S_0 - S_1	S_2	S_3
P_0, P_1	C_2 - C_3	C_3 - C_4	C_4	C_3	C_4	C_5	C_3 - C_4	C_5	C_5
P_2	C_3 - C_4	C_3 - C_4	C_4 - C_5	C_4	C_4	C_5	C_4 - C_5	C_5	C_5
P_3	C_4	C_4 - C_5	C_4	C_5	C_5	C_5	C_5	C_5	C_5

Definition of corrosivity categories C_1 to C_5 is given in Table 21. See Table 20 for wetness classifications τ_1 - τ_5 . See Table 19 for SO_2 classifications S_0 - S_3 .

Equation 10 determines the 1 year corrosion loss for flat specimens. The results summarize all of the CORRAG data. For steel and copper, the R^2 values are 0.63 and 0.58, respectively. Zinc and aluminum have R^2 values less than 0.5. Given the environmental data for a particular location, Eq 10 may be used to predict the amount of corrosion in 1 year. In comparison, Eq 6 to 9 are an improved version of Eq 10.

Additional results from a study conducted in Vietnam are shown in Table 25 (Ref 32). The authors compared predicted corrosion rates with those measured for three models. The first model (a) used the average environmental data for the test years July 1995 through July 1998. Percent differences varied from -13 to 13.5%. For the second model (b), the same environmental data were used as in (a), except that the chloride concentration was ignored. For this case, the percent differences varied from +1 to -15%. The results suggested that for these tests and locations, chloride content was not a significant factor. For the third model (c), the authors used the average environmental data from January 1996 through December 1999, and for this case, the percent difference between measured and calculated varied from 0 to -19%.

For the Vietnamese study, the initial equation used to describe the 1 year corrosion is similar to

Table 19 Classification of sulfur compounds based on sulfur dioxide (SO_2) and airborne salinity contamination (Cl) according to ISO 9225

Table 24 Coefficients for the ISO CORRAG program linear regression analysis (Eq 10)

Metal	b ₀	b ₁	b ₂	b ₃	R ²
Fe	3.647	0.011	0.137	0.833	0.63
Zn	0.388	0.010	0.126	0.552	0.49
Cu	0.354	0.005	0.148	0.702	0.58
Al	−1.972	0.014	0.233	0.225	0.39

Source: Ref 29

Eq 10, except that a relative humidity term (RH) is included. Because the Cl[−] content did not have much of an effect, the final equation follows and does not include the Cl[−] term:

$$r_{\text{corr}} = -8.78T + 5.25RH + 0.0081TOW - 10.228 \quad (\text{Eq 11})$$

$$R^2 = 0.94$$

where r_{corr} is the corrosion after 1 year of exposure [g/(mm² · yr)], T is the annual average

Sontay	289.74	255.15	13.50

(a) Using the average environmental data July 1995 to July 1998 (during the exposure time). (b) Same as (a) but without chloride concentration. (c) Using the annual average environmental data Jan 1996 to Dec 1999. Source: Ref 32

Table 26 Results of measurements of contaminants in the rust by energy-dispersive spectroscopy (EDS) and by chemical analysis of water extracts after leaching in distilled water

Test site	Thickness of the rust		Composition (by EDS), wt%		Soluble salts, mg/m ²	
	μm	mils	Sulfur	Chlorine	Sulfates	Chlorides
Escorial	59.5	2.34	0.66	0.06	562	723
Madrid	93.0	3.66	0.74	0.41	974	1117
Bilbao	124.5	4.91	0.85	0.07	1410	756
Barcelona	111.0	4.37	0.78	1.03	1203	2237

Source: Ref 34

temperature (°C), RH is the annual average relative humidity (%), and TOW is the time of wetness (h/yr).

Corrosion Products

A study in Sweden examined the corrosion products formed on zinc panels that were rain sheltered. The locations had varying amounts of SO_4^{2-} and Cl^- in the atmosphere. The compositions of the different compounds formed on the zinc are shown in Fig. 25 (Ref 33). The upper left portion of the figure shows the compounds formed under low SO_4^{2-} and Cl^- concentrations, while the lower right portion of the figure identifies the compounds formed under the highest concentrations of SO_4^{2-} and Cl^- .

Examination of rust layers formed on steel in four locations in Spain is shown in Table 26 (Ref 34). The study examined the rust layer using energy-dispersive spectroscopy and analyzing soluble salts extracted from the rust layers. The thickness of the layers increased in going from

Escorial, Spain (rural), to Barcelona, Spain (marine). Similarly, the chlorides showed a percentage increase in going from the rural to the marine environment.

Atmospheric Corrosion Test Sites

Table 27 provides a list of atmospheric corrosion sites throughout the world. Where available, the 2 year corrosion rates for low-carbon steel and zinc are given. Some of the sites have a marine corrosion index and/or an atmospheric corrosion index number after them. The higher the index numbers, the more aggressive the environment (Ref 2).

Corrosion of Metallic Coatings

Barbara A. Shaw, Wilford W. Shaw, and Daniel P. Schmidt, Department of Engineering Science and Mechanics, The Pennsylvania State University

A SACRIFICIAL COATING applied to a steel substrate can add 20 years or more of life to the substrate, depending on its thickness and composition. Different techniques to apply sacrificial coatings offer various characteristics that contribute to corrosion resistance. Several of these techniques and the corrosion attributes of the respective coatings are discussed in this article.

Thermal Sprayed Coatings

A wide variety of materials such as aluminum, zinc, and their alloys can be applied via thermal spraying and have proved to significantly extend substrate lifetimes cost effectively. Their effectiveness in combating corrosion has been evaluated in several long-term studies (Ref 1–5), which have revealed that depending on composition and thickness, these coatings are capable of providing complete protection of steel substrates for 50 years. In 1951, a Cambridge University study under the direction of T.P. Hoar was initiated on over 1500 steel panels thermal sprayed with the following materials (Ref 1):

Mixed powders and alloy powder coatings (0.08 mm, or 3.2 mils), wt%

90% Zn + 10% Al
80% Zn + 20% Al
70% Zn + 30% Al
60% Zn + 40% Al

A report was issued after 34 years of marine exposure in the 250 m (800 ft) lot in Kure Beach, NC, revealing that the aluminum powder thermal coatings and the layered zinc/aluminum and aluminum/zinc powder thermal spray coatings showed no base metal corrosion or rust staining of the thermal spray coatings after 34 years. A comparison of the performance of the pure metal coatings evaluated in this study after 34 years of exposure is presented in Fig. 1. When observed in August 2001, almost 50 years after initial exposure at the 250 m (800 ft) marine atmospheric site, the 0.08 mm (3 mils) and 0.15 mm (6 mils) thermal spray aluminum coatings were fully intact with only a small amount of rust staining noted on the 0.08 mm (3 mils) panel at a cut edge and no rust or rust staining noted on the thicker coating as shown in Fig. 2.

Another, well-known study of thermal spray coatings was initiated slightly later in the

Fig. 1 Percent of area corroded on single-element powder thermal spray coatings after 34 years of marine atmospheric exposure in the 250 m (800 ft) lot at Kure Beach, NC. Source: Ref 1

1950s by the American Welding Society (AWS). The AWS study included aluminum and zinc wire-flame-spray coated steel specimens with coating thicknesses of 0.08, 0.15, 0.23, 0.30, and 0.40 mm (3, 6, 9, 12, and 15 mils). Field exposures were conducted at a variety of atmospheric exposure sites and two seawater immersion sites. The study was scheduled to last 12 years, but because the coatings were doing so well, the exposure period was extended to 19 years. Results of this 19 year study are presented in a 1974 report (Ref 2). After 19 years of marine atmospheric exposure, the flame sprayed aluminum coated steel panels showed no rusting of the steel substrates. Over 4000 specimens were included in this study, which found that 0.08 to 0.15 mm (3 to 6 mils)-thick thermal sprayed aluminum coatings (either sealed or unsealed) provided complete protection to steel substrates

in seawater, severe marine atmospheric, and industrial atmospheres. Some blistering and rust staining of the aluminum coating on unsealed panels were noted. Thermal sprayed zinc coatings were also capable of providing 19 years of protection to steel substrates, but a minimum of 0.30 mm (12 mils) was required for seawater exposures and 0.23 mm (9 mils) of unsealed zinc or 0.08 to 0.15 mm (3 to 6 mils) of sealed zinc for marine and industrial atmospheres.

A Navy study was undertaken in the mid 1980s of flame and arc-sprayed aluminum, zinc, prealloyed zinc-aluminum, and duplex zinc/aluminum coatings in marine atmospheric, splash and spray, and immersion environments. More than 600 coated panels were exposed. The thermal spray coatings were applied to both steel and 5086 aluminum substrates. The thermal spray coatings were tested in both sealed and painted conditions and as-deposited without any sealer or paint systems conditions. In addition, both commercial and military suppliers prepared specimens. The study revealed that when deposited under controlled conditions (using either military or commercial facilities), both flame and arc sprayed aluminum coatings (0.18 to 0.25 mm, or 7 to 10 mils, thick sealed and painted) provided excellent protection of steel substrates exposed to marine environments for the duration of the study (68 months). Figure 3 compares the condition of the flame and the arc sprayed aluminum-coated steel to painted steel after 42 months of severe marine atmospheric exposure (25 m, or 80 ft, lot at Kure Beach, NC) Visually, the painted steel, which had been scribed, was heavily corroded with blisters covering the majority of the exposed surface. On the other hand, the flame and arc-sprayed aluminum, which were also scribed, were free of base metal corrosion or degradation of the sprayed metal coatings. The appearance of the flame and arc-sprayed panels was the same at the end of the exposure period (after 68 months) (Ref 6).

The U.S. Army Corps of Engineers conducted a long-term study of coated pilings exposed in the waters of Buzzard's Bay Maine (the bottoms of the coated pilings were driven into the bottom of the bay, exposing the column to mud, immersion, tidal, splash and spray, and atmospheric conditions) (Ref 7). The 21 pilings contained coatings including zinc-rich primers with various topcoats, as-deposited flame sprayed zinc, as-deposited flame sprayed aluminum, and flame sprayed zinc and aluminum with sealers and topcoats. Bare steel was included as a control. After 18 years, the flame sprayed aluminum coatings with a vinyl wash primer and sealer performed the best of all the coatings evaluated in this study.

The ability of a sacrificial coating (thermal sprayed or otherwise deposited) to provide protection to the substrate at defects in the coating is of significant importance. Often, exposure testing includes damaged or scribed panels, and assessment of these damaged areas is included in the inspection protocol. One method to quantify the corrosion damage in the scribed area of top coated/scribed specimens is the "Navy Scribe and Bold Surface Inspection Practice" (Ref 8). This technique, described in Table 1, involves dividing the scribe into segments (as shown in the accompanying figure in Table 1), and at each segment the minimum and maximum lateral creepage of corrosion are measured (in mm) and then added together. This number is referred to as the *segment value creep* and is used to find the corresponding "rating" in Table 1. The next rating is made by measuring the minimum and

maximum lateral creepage of corrosion over the entire scribe (in mm) and adding these numbers together. This number is referred to as the *maximum and minimum creep value* and is used to find the corresponding *rating number* in Table 1. A third rating is then made using ASTM D 1654 (Ref 9) by estimating the percent of the panel surface that exhibited corrosion blistering (a 1/2 in. band around the edge of the panel and corrosion associated with the scribe were excluded from the rating). The three ratings can then be averaged together or used separately to assess a coating systems ability to provide protection. The way in which the damage is introduced to test panels can have a significant impact on the type of results obtained. No matter what approach is used, a quantifiable, easily reproducible method in which the underlying substrate is exposed is needed.

Electrochemical techniques are also being used to assess the long-term durability and mechanisms of protection of sacrificial thermal spray coatings. These studies have identified the deleterious effects of porosity, oxide layers within the deposit, embedded grit blasting media, and thin areas in the coating. Electrochemical methods used to investigate thermal spray coatings typically include: corrosion potential versus time measurements, anodic and cathodic polarization, polarization resistance measurements, and most importantly, electrochemical impedance spectroscopy (EIS). Electrochemical impedance spectroscopy, especially the maximum impedance at lowest frequency, is useful for investigating degradation of sealed and or sealed and painted thermal spray coatings. In-situ electrochemical measurements are also now being conducted from time to time on field exposed panels such as the EIS interrogation of defect sites on the marine atmospheric exposures shown in Fig. 4.

Description of Thermal Spray Processes

Sprayed metal coatings can be defined as processes that deposit fine metallic materials onto a prepared substrate. Sprayed metal processes have these major advantages: a wide variety of materials can be used to make coatings, a coating can be applied without significant heating of the substrate, and the coating can be replaced without changing the properties or dimensions of the part. Sprayed metallic coatings are limited, however, only to substrates in direct view and size limitations of the equipment prohibit coating small deep cavities or crevices where the spray gun or nozzle will not fit.

Although all spray deposition processes can be classified as thermal spray technologies, there are two fundamental types: those that deposit the coating in the molten state, as illustrated in Fig. 5, and those that deposit the coating in a warm state. Conventional thermal spray processes, which deposit the materials in a molten state, include: high-velocity oxyfuel (HVOF), plasma, flame, laser cladding, and electric arc

deposition. Conversely, high-velocity particle consolidation (HVPC) only warms the metal particles and uses supersonic velocities to accelerate particles onto the substrate surface. In the HVPC process, compressed gas at pressures between 1 and 3 MPa (145 and 435 psi) expand when passed through a de Laval nozzle yielding exit speeds up to 1200 m/s (4000 ft/s). Metallic powder is introduced into the gas flow accelerating particles to velocities between 18 and 1000 m/s (60 and 3300 ft/s) depending on particle size and the material. A gas heater is used to increase gas temperature. Exposing particles to heated gas increases ductility and improves deposition efficiency. Figure 6 shows a schematic of the HVPC equipment and a photograph of the robotic nozzle (Ref 10). Upon impact, the solid particles deform and bond with the substrate. Repeated impact causes particles to bond with particles already deposited, resulting in a uniform coating with very little porosity (values <3% are typical). The fundamental difference between HVPC and other thermal spray processes is that HVPC applies material particles in the solid state, whereas other conventional

thermal spray methods such as wire flame spray and wire arc spray deposit particles in the molten state (Ref 10). The HVPC process has some advantages over conventional thermal spray processes. The lower deposition temperature is advantageous for some materials such as aluminum substrates and gives the ability to produce coating mixtures that otherwise may not be feasible (Ref 10). Oxide contamination within the coating, as pictured in Fig. 7, is greatly reduced. Extremely thick coatings, millimeters thick, are possible to produce. In addition, residual stresses are reduced and the powders can be recycled because they are not significantly heated (Ref 10). Limitations include: the process can use only powders, high deposition rates limit the substrate material that can be coated, high gas pressure and flow rates are required, the objects to be coated must be placed 25 mm (1 in.) from the exit plane of the de Laval nozzle, and one of the constituents must be ductile (Ref 10). As in other sprayed metal coating techniques, only areas in line-of-sight can be coated.

Hardness, Density, and Porosity. In comparison with paint, thermal spray coatings have a

high hardness. This hardness is often less than that of the initial feedstock and is dependent on the coating material, equipment used, and choice of deposition parameters. Detonation spraying, HVOF, plasma spray, arc spray and flame spraying rank from the highest particle velocity process (highest density and hardness) to the lowest particle velocity (lowest density and hardness). Other factors, such as thermal spray process and application parameters, also have a significant influence on porosity.

The porosities of flame sprayed coatings may exceed 15% as a result of oxidation that occurs because of the oxidizing potential of the fuel-gas mixture in the flame spraying (Ref 11). An optical micrograph showing these oxide layers for a flame sprayed aluminum coating is presented in Fig. 7. This porosity can have a significant influence on the corrosion resistance of the coating. If left unsealed, surface connected porosity provides a path for aggressive species into the coating as illustrated in Fig. 8, which shows an electron probe dot-map revealing chloride along the oxide layers within unsealed aluminum spray (Ref 12).

Thickness. The sprayed metal coatings are normally applied to a thickness of 75 to 180 μm (3 to 7 mils) to provide adequate corrosion protection. The thickness of the coating is selected to limit interconnected porosity (too thin a coating) and to minimize thermal expansion mismatch (too thick a coating) with the substrate, which could result in bond-line separation (Ref 13). For marine applications, thermal sprayed aluminum coatings 180 to 250 μm (7 to 10 mils) thick are used in order to limit through porosity (Ref 14).

Adhesion of typical thermal spray coatings is similar to that of organic coatings with adhesion values ranging from 5.44 to 13.6 MPa (0.8 to 2 ksi) (Ref 15) when measured in accordance with ASTM D 451. However, specialized wear-resistant coatings with high tensile adhesive strengths in excess of 34 MPa (5 ksi) as measured by ASTM C 633 can be produced by the thermal spray processes with the higher particle velocities (Ref 15).

Imperfections. The arc spray and flame spray processes accelerate molten metal material

from powder, wire, or rod in a gas stream and project the molten metal onto a suitably prepared substrate. Upon impact with the substrate, the molten droplets rapidly solidify to form a thin “splat” (Ref 16) as shown in Fig. 5. Thin overlapping and interlocking particles forming the coating characterize this splat. The coating is built up by successive impingement and interbonding among splats as illustrated in Fig. 5 and 7. Imperfections originate from “unmelted” particles that are not totally molten, large particles that are bigger than the median size, low velocities, oxidation of particles, and fragmented splats (Ref 16). Note that voids and oxides form an interconnected network within the coating, allowing the environment to eventually work its way through the coating, if the coating is not sealed and/or painted. In addition to the thickness and composition of these coatings, the microstructure can be extremely varied. Materials deposited may be in thermodynamically metastable states, and the grains within the splats may be sub-micron-size or even amorphous (Ref 17). This ultrafine-grained microstructure leads to an anisotropy of the coating in the direction perpendicular to the spray direction (Ref 16). Despite their being fine grained, the thermal sprayed microstructures have an abundance of imperfections comprising a variety of particle sizes, volume densities, morphologies, and sometimes orientations (Ref 16). Micrographs of a few common imperfections in thermal spray coatings are presented in Fig. 9.

Sealing and Topcoat. A standard practice is to seal the thermal spray coating with low-viscosity sealers because the metal coating is inherently porous. Once the thermal spray

Fig. 8 Electron microprobe x-ray scans of flame-sprayed aluminum coating cross sections after full immersion in filtered seawater for 15 months

sacrificial coatings are applied, the sealer is applied. The sealer is used to penetrate the pores of the spray metal coating and to resist migration of atmospheric corrosives through the sacrificial coating to the substrate material. The sealer is normally sprayed or brushed on, and it penetrates and fills the pores. Sealers should also be used in acidic or alkali environments (Ref 13). Vinyl and thinned epoxies are typical sealers. For high-temperature applications, a silicone alkyd sealer is used (Ref 18). One typical sealer is a two-component epoxy polyamide sealant designed to increase protection of metallic thermal spray coatings up to 150 °C (300 °F). It exhibits

resistance to corrosion in industrial and marine atmospheres. This sealer meets governmental specifications designated in MIL-P-53030A (Ref 19). The sealer is both lead- and chromate-free and contains no more than 340g/L of volatile organic compounds. After the two-part epoxy is thoroughly mixed and diluted with 7 parts de-ionized water, it is applied by an airless sprayer to a recommended wet film thickness of 0.2 mm (8.0 mils), yielding a 0.05 mm (2.0 mils) dry thickness (Ref 19). Maximum performance by the sealer occurs when coating surfaces are clean, dry, and free of foreign matter. The sealer is dry to touch after 45 min and complete air cure

takes 7 days (Ref 19). Finally, finish coating layers (water or solvent reducible primer/topcoat combinations) are applied. The primer is applied on top of the sealer to aid in adhesion of the paint to the remaining coating system. Available primers include water or solvent reducible, air-drying, and corrosion-inhibiting primers. A typical coating system, illustrating the various layers in the system, is presented in Fig. 10.

Hot Dip Coatings

Galvanizing has been used extensively for protection against marine environments and approximately 40 million tons of steel are hot-dip galvanized each year (Ref 20). The advantages associated with applying zinc by thermal spray versus galvanizing makes the former method attractive for certain applications and the latter attractive for others (Ref 21). Hot dip galvanizing produces a fully dense coating that is metallurgically bonded to the substrate. In galvanizing, the size of the part, heat distortion, ease of application, and the thickness and uniformity of the coating are factors that must be considered. The thickness of galvanized coatings can vary from less than 25 to 200 μm (<1 to 8 mils) and should be selected depending on the environment to be experienced and the desired lifetime. A range of zinc coating processes, including hotdipping, and their respective coating lifetimes are presented in Fig. 11 (Ref 20). Thick galvanizing and thermal spray were the

only protection methods recommended by the British Standards Institution for providing long-term corrosion protection in a polluted marine atmosphere (Ref 21). The American Society for Testing and Materials (ASTM) exposed galvanized sheet specimens in two marine environments—Sandy Hook, NJ, and Key West, FL—in 1926 and reported that panels with a coating weight of 760 g/m² (2.5 oz/ft²) of zinc first showed rust after 13.1 and 19.8 years of exposure, respectively (Ref 22). An extensive study of the atmospheric corrosion of galvanized steel at the 250 m (800 ft) lot at Kure Beach, NC, resulted in predicted weight losses after 10 years of 103 g/m² and 55 g/m² for skyward and groundward marine exposures, respectively (Ref 23). Most investigators agree that the life of a zinc coating is roughly proportional to its thickness in any particular environment and is independent of the method of application.

Hot dip aluminum coatings, or aluminized coatings, are also used for the corrosion protection of steel in marine environments. An extensive comparative study was conducted on the atmospheric corrosion behavior of aluminized and galvanized steels (Ref 24, 25). Table 2 shows predicted 10 year weight losses of both of these coatings based on exposures conducted in the 250 m (800 ft) lot at Kure Beach, NC.

Table 2 Predicted 10 year corrosion rates for galvanized and aluminized steel panels

Tested 250 m (800 ft) from the ocean at Kure Beach, NC

Coating	Predicted weight loss, g/m ²	
	Skyward exposure	Groundward exposure
Galvanized	103.3	55.2
Type 1 aluminized (Al-Si)	17.8	20.1
Type 2 aluminized (pure aluminum)	11.6	17.9

Source: Ref 26

ASTM conducted a further comparison of the atmospheric-corrosion behavior of aluminized and galvanized panels. After 20 years of marine atmospheric exposure (250 m, or 800 ft, lot, Kure Beach, NC), many of the galvanized steel panels were showing rust, but consistently good results were reported for the aluminized coating, which showed only minor pinholes of rust (Ref 26). Since 1972, a commercially produced aluminum-zinc (55Al-1.5Si-43.5Zn) hot dip coating has also been available for the corrosion protection of steel. After 13 years, good long-term corrosion resistance has been reported for 55Al-1.5Si-43.5Zn hot dip coatings in industrial and marine atmospheres. Corrosion-time curves for 55Al-1.5Si-43.5Zn hot dip coatings in these atmospheric environments are presented in Fig. 12. The advantages of hot dip aluminum coatings are discussed in (Ref 27). The corrosion behavior of aluminum coatings obtained from aluminizing baths of various compositions was studied in laboratory tests. Aluminized coatings containing manganese were suggested as possible candidates for corrosion protection for coastal structures and deep-sea oil rigs. More information on hot dip galvanized and aluminized coatings are available in the articles “Continuous Hot Dip Coatings” and “Batch Process Hot Dip Galvanizing” in Volume 13A.

Electroplated Coatings

Electroplated zinc or cadmium is the standard coating used to provide corrosion protection to steel fasteners in the marine environment. The cadmium coating is used because of its hardness, close dimensional tolerance, and barrier to hydrogen permeation into or out of steels (Ref 28). The disadvantages of cadmium plating are its short life (for example, 4 months) in the marine atmospheric environment and concerns about occupational health due to the toxicity in

the plating process. Zinc plating also has a short service life. A comparison of zinc and cadmium coatings in industrial and marine sites (Fig. 13) illustrates the importance of zinc in marine environments. Alternatives for zinc plating include ion vapor deposited aluminum and paints containing zinc or aluminum pigment in a ceramic binder. These coatings, including zinc with a potassium silicate binder and aluminum with a phosphate-chromate binder, exhibit excellent corrosion protection for fasteners (minimum 1 year marine protection) (Ref 29). They are normally applied by conventional hand spraying.

Methods for electroplating aluminum are still in development, although plating using an organic aprotic solvent is a promising process (Ref 30). In laboratory polarization and galvanic tests, ion-deposited aluminum coatings performed well, indicating their potential for use on aircraft fasteners (Ref 31). Corrosion tests of zinc and aluminum coatings used for aircraft fastener applications showed variable results (Ref 32). Aluminum and zinc pigmented coatings performed better than electroplated zinc, ion vapor deposited aluminum, and electroplated cadmium on steel fasteners in laboratory seawater immersion tests (Ref 28). However, hydrogen permeability through the coating, as well as the corrosion performance of the coating, must be considered for a given fastener application (Ref 31).

Methods of Protection

Aluminum Coatings. Corrosion protection of aluminum-coated steel arises from the excellent corrosion resistance of the bilayer protective film on the aluminum surface, the barrier properties of the aluminum layer, and the cathodic protection of the exposed steel with the aluminum coating acting as a sacrificial anode

Fig. 12 Corrosion-time plots for hot dip zinc, zinc-aluminum (55Al-1.5Si-43.5Zn), and aluminum-coated steel in (a) marine atmosphere (Kure Beach, NC: 250 m, or 800 ft, lot), (b) severe marine atmosphere (Kure Beach, NC: 25 m, or 80 ft, lot), and (c) industrial atmosphere (Bethlehem, PA)

Fig. 13 A comparison of corrosion rates of zinc and cadmium in marine, urban, and industrial atmospheres. Source: Ref 20

(aluminum being more active than steel in the galvanic series). The sprayed aluminum coatings do not provide as much protection at defects as zinc coatings, but the protection that is provided will last longer. Aluminum owes its excellent corrosion resistance to the barrier oxide film that is strongly bonded to its surface. If damaged, this film often has the ability to immediately repassivate itself. The oxide film is composed of two layers: next to the metal surface is a thin amorphous oxide barrier layer and covering the barrier layer is a thicker, more permeable outer layer of hydrated oxides. The protective film in aluminum is stable in chloride-free environments at neutral pH values of 4 to 9. At higher or lower pH values and in the presence of chlorides, the protective passive film is subject to localized breakdown such as pitting. Once outside the passive window, aluminum corrodes in aqueous solutions because its oxides are soluble in many acids and bases.

Zinc Coatings. Corrosion protection in zinc-coated steel arises from the barrier action of the zinc layer, the secondary barrier action of the zinc corrosion products, and the cathodic protection of exposed steel with the coating acting as a sacrificial anode (Ref 33). First, the barrier action of the zinc is made possible because zinc is ten to a hundred times more corrosion resistant than steel in atmospheric environments (Ref 34). This initial film is backed up by the secondary barrier action of corrosion products. The corrosion products that form in the beginning are loosely attached to the surface. Gradually, they become more adherent and dense. This layer is a precipitate (zinc hydroxide). The third way that zinc metallic coatings provide corrosion protection is through cathodic protection. At voids in the coating, such as scratches and at edges, the zinc behaves as a sacrificial anode, thus providing galvanic protection (Ref 35). The zinc surface will preferentially corrode at a slow rate, thus protecting the steel. This is a result of the zinc's being a more active metal in both the electromotive force (EMF) and galvanic series compared with the iron or steel. With this three-way defense, zinc metallic coatings sacrificially

protect structural steel in corrosive environments and extend the lifetime of equipment.

Three main features of a zinc coating that are pertinent to its effectiveness are thickness, composition, and microstructure. Coating thickness is a key factor in determining coated product performance. In general, thicker coatings provide greater corrosion protection, whereas thinner coatings tend to give better formability (Ref 36). In one study (Ref 37), it was shown that plating thickness was the prime factor in assessing the corrosion performance of zinc coatings. The corrosion resistance of zinc-plated steel was found to be directly proportional to zinc thickness (Ref 37). It was also found (Ref 11) that the corrosion loss of hot-dip zinc coatings was considered to be linear, thus the lifetime of a zinc coating is proportional to its thickness.

In addition to thickness, another important feature of zinc coatings is their composition. In order to provide the most protection, zinc coatings must be as dense and as continuous and smooth as possible. Zinc coatings last longer if the corrosion of the surface is uniform. With a rough surface, localized corrosion is more evident and, therefore, a smooth coating is desired. The more compact and continuous the coating layers, the smaller the active surface area within the pores will be and thus the smaller the observed corrosion rate (Ref 38). Defects in the coating can always be present due to the substrate porosity, and these will be of different types and extents depending on the kind of deposition treatment employed. One study (Ref 39) showed that the presence of flaws (porosity and microcracks) was more important than the crystallographic orientations for the corrosion resistance of zinc coatings. These flaws hindered the barrier protection of zinc that the coating usually provides. In another study, it was found that zinc corrosion centers initially formed on the areas where the film was the weakest (thin, more porous) (Ref 37). This is all evidence that the most desirable composition for zinc coatings is a homogeneous, smooth, and dense coating.

A third feature that also plays a role in providing protection is the coating's microstructure. The study described in Ref 39 discovered that zinc crystal planes with different orientations corrode at different rates. This is associated with variances in zinc single crystal corrosion rates because of differences in planar packing density. The activation energy for dissolution was suggested to increase as the packing density increases (Ref 39). The researchers also showed a correlation between texture and corrosion behavior, suggesting that the 001 basal plane is the most resistant to corrosion (Ref 39). Another study (Ref 40) states that the characteristic texture of unalloyed zinc is basal planes parallel to the surface, which provides for bright, smooth crystals. This study also states that although coating corrosion resistance is particularly dependent on the zinc film chemical composition, crystallographic orientation also influences coating corrosion resistance. It further showed

that the preferred crystallographic orientation (texture) depends mainly on external factors such as cooling rate gradient and surface conditions of the steel substrate (Ref 40). Impedance spectra provided information that the lower surface energy of bright crystals (due to their smooth surface and smaller amount of surface-segregated elements) caused the degree of corrosive attack to be significantly less (Ref 40). This all demonstrates the important roles that zinc thickness, composition, and microstructure have in providing corrosion protection of steel.

Performance of Organic Coatings

Revised by R.D. Granata, Florida Atlantic University

ORGANIC COATINGS are the principal means of corrosion control for the hulls and topsides of ships and for the splash zones on permanent offshore structures. Most stationary offshore oil industry platforms are not painted below the waterline, and most marine pipelines are factory coated with special proprietary coatings (see the articles "Corrosion in Petroleum Production Operations," and "External Corrosion of Oil and Natural Gas Pipelines" in this Volume).

Figure 1 shows the marine environments that are destructive to shipboard coatings. Similar environments are found on offshore oil production platforms (Fig. 2), lighthouses, docks, and other marine structures.

Before the 1960s, most marine coatings were fairly simple and could be applied by laborers such as seamen or maintenance personnel. Although the advent of high-performance marine coatings in the 1960s changed this, the

performance of marine coatings has improved to such an extent that topside coating lifetimes of 20 years have been experienced on some offshore oil production platforms. During the 1980s, environmental issues drove the development of compliant coatings based on new chemistries and technologies. The coatings that resulted required rapid assessment of performance expectations and field validations. Many high-performance coatings are now available for marine service. Some highly specific and detailed information related to preservation of naval vessels is contained in a Department of Navy, Commander Military Sealift Command document COMSC Instruction 4750.2C (Ref 1).

Surface Preparation

Proper surface preparation is the most important consideration in determining the perfor-

mance of organic coating systems. Surface cleanliness and proper surface profile are both important. Surface preparation frequently accounts for two-thirds of total painting costs for offshore structures.

The Society for Protective Coatings (formerly the Steel Structures Painting Council, SSPC), NACE International (formerly the National Association of Corrosion Engineers), and standards groups in Sweden, Germany, the United Kingdom, and Japan have all issued standards for surface preparation. Examples of these are listed in Table 1. Wet abrasive blast cleaning and waterjetting (waterblasting) are not yet included in the standards, but are now being extensively used. Wet blasting is useful for dust control and for avoiding electrical sparking in class I (explosive) areas. Generally, a small amount of nitrite inhibitor is added to the water to prevent rerusting before priming.

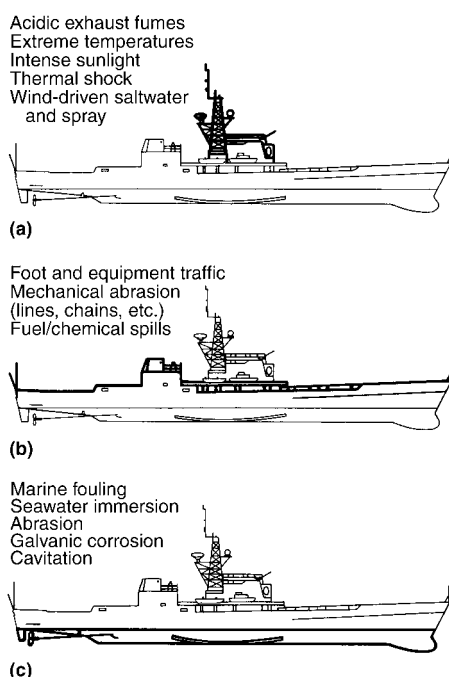

Fig. 1 Environments that are destructive to shipboard coatings. (a) Antennas and superstructures. (b) Deck areas. (c) Underwater hull

Fig. 2 Zones of severity of environment for a typical offshore drilling structure. UV, ultraviolet

Waterjetting can be used around rotating equipment, such as pumps, turbines, and generators; underwater; and in class I areas. No grit is used; therefore, few solids result that could harm equipment. Waterjetting with 34.5 to 138 MPa (5 to 20 ksi) of pressure will remove all but the most adherent paint and oxide scale and, once the surface is blown dry, provides an excellent surface for painting. Waterjetting with detergent in the water at lower pressure is a good alternative to solvent washing for preparing oily and greasy surfaces for painting.

Grit blasting is usually used for surface preparation for marine coatings. The severe corrosion exposure conditions in offshore and coastal locations require the best possible surface preparation.

Inorganic zinc primers, which are frequently used in marine applications, require white metal grit blasting to remove all surface contamination because inorganic zinc has both a chemical bond and a mechanical bond to the surface. Epoxy primers can be applied over commercial grade surfaces for land-based exposures, but require near-white metal surfaces to maintain performance offshore.

Table 2 lists the characteristics of several types of grit. Grit that is used offshore is not recoverable; this limits the economical choices. Some types are too expensive unless they can be recycled. Silica sand is generally not used because of the possibility of silicosis, its friable nature, and its rounded shape, which is not con-

ducive to high productivity. Safety issues related to surface preparation should be given due consideration including: abrasive dust toxicity, for example, silicosis; surface coating and substrate toxicity, for example, lead, chromate, organotin coatings, and pigments; and, explosion hazard, for example, plastic and organic media dust.

Topside Coating Systems

Organic coatings are usually composed of three components: binders (resins), pigments, and solvents. Not all paints, however, have all three components. For example, solventless paints have been developed in response to environmental restrictions on the use of volatile solvents. Solventless paints can be applied at thicknesses to 13 mm (1/2 in.); such thick films would not be possible in a paint containing volatile solvents, because the thickness of the film would prevent solvent evaporation.

Paints can be classified by the type of binder or resin into categories:

- Air-drying oils (for example, linseed oil, alkyds)
- Lacquers (vinyls, chlorinated rubbers)
- Chemically cured coatings (epoxies, phenolics, and urethanes)
- Inorganic coatings (silicates)

The article "Organic Coatings and Linings" in Volume 13A of the *ASM Handbook* contains

detailed information on the formulation of all of these types of organic coatings.

Primers

The primer is by far the most important coat in the protection of steel substrates. The primary function of subsequent coats is to protect the primer and to give color and a pleasing appearance.

Inhibitive primers contain substances that resist the effects of contaminants on the steel, such as rust and salt, and that resist disbondment under corrosive conditions and cathodic protection. Formerly, lead pigments and chromates were used as inhibitors, but this is no longer the case, because of tightened environmental regulations that prohibit or severely restrict their use. The inhibitors currently in use include a number of proprietary compounds, some of which enable coating service lifetimes approaching that associated with restricted lead and chromate pigments.

Zinc-Rich Primers. The introduction of coatings containing a high percentage of metallic zinc is an important development in protective coatings in the last 50 years. Zinc dust is loaded into both organic and inorganic binders to form primers that are extremely effective in the prevention of corrosion, underfilm creepage, and coating system failure.

Inorganic zinc-rich primers are based on various silicate binders. There are several

Table 1 Uses and applicable standards for various surface preparation techniques

Technique	Applicable standards	Uses
Solvent cleaning	SSPC-SP1	Used to remove oil, grease, dirt, soil, drawing compounds, and various other contaminants. Does not remove rust or mill scale. No visual standards are available.
Hand tool cleaning	SSPC-SP2	Used to remove loose rust, mill scale, and any other loose contaminants. Standard does not require the removal of intact rust or mill scale. Visual standards: SSPC-VIS 3—BSt3, CSt3, and DSt3(a)
Power tool cleaning	SSPC-SP3	Same as hand tool cleaning. Visual standards: SSPC-VIS 3—BSt3, CSt3, and DSt3(b)
White-metal blast cleaning	SSPC-SP5; NACE 1	Used when a totally cleaned surface is required; blast-cleaned surface must have a uniform, gray-white metallic color and must be free of all oil, grease, dirt, mill scale, rust, corrosion products, oxides, old paint, stains, streaks, or any other foreign matter. Visual standards: SSPC-VIS 1—ASa3, BSa3, CSa3, and DSa3(a); NACE 1
Commercial blast cleaning	SSPC-SP6; NACE 3	Used to remove all contaminants from surface, except the standard allows slight streaks or discolorations caused by rust stain, mill scale oxides, or slight, tight residues of rust or old paint or coatings. If the surface is pitted, slight residues of rust or old paint may remain in the bottoms of pits. The slight discolorations allowed must be limited to one-third of every square inch. Visual standards: SSPC-VIS 1—BSa2, CSa2, DSa2(a); NACE 3; SSPC-VIS 5/NACE VIS 9(d)
Brush-off blast cleaning	SSPC-SP7; NACE 4	Used to remove completely all oil, grease, dirt, rust scale, loose mill scale, and loose paint or coatings. Tight mill scale and tightly adherent rust and paint or coatings may remain as long as the entire surface has been exposed to the abrasive blasting. Visual standards: SSPC-VIS 1—BSa1, CSa1, DSa1(a); NACE 4
Pickling	SSPC-SP8	Used for complete removal of all mill scale, rust, and rust scale by chemical reaction, electrolysis, or both. No available visual standards
Near-white blast cleaning	SSPC-SP10; NACE 2	Used to remove all oil, grease, dirt, mill scale, rust, corrosion products, oxides, paint, or any other foreign matter. Very light shadows, very slight streaks, and discolorations caused by rust stain, mill scale oxides, or slight, tight paint or coating residues are permitted to remain but only in 5% of every square inch. Visual standards: SSPC-VIS 1—ASa2-1/2, BSa2-1/2, CSa2-1/2, and DSa2-1/2(a); NACE 2; SSPC-VIS 5/NACE VIS 9(d)
Power tool cleaning to bare metal	SSPC-SP11	Used to completely remove all contaminants from a surface using power tools. Equivalent to SSPC-SP5, "White-Metal Blast Cleaning." Requires a minimum 1 mil anchor pattern. Visual standard: SSPC-VIS 3(b)
Waterjetting	SSPC-SP12; NACE 5	Cleaning using high- and ultrahigh-pressure waterjetting prior to recoating. Visual standard: SSPC-SP4/NACE 7. Photos depict degrees of cleanliness and flash rusting(c)
Mechanical, chemical, or thermal preparation of concrete	SSPC-SP13; NACE 6	Prepares cementitious surfaces for bonded protective coating or lining systems
Industrial blast cleaning	SSPC-SP14; NACE 8	Used to clean painted or unpainted steel surfaces free of oil, grease, dust, and dirt. Traces of tight mill scale, rust, and coating residue are permitted. Visual standard: SSPC-VIS 1(a)
Commercial grade power tool cleaning	SSPC-SP 15	Used for power tool cleaning of steel surfaces while retaining or producing a minimum 25 µm (1 mil) surface profile. This standard requires higher degree of cleanliness than SSPC-SP 3, but allows stains of rust, paint, and mill scale not allowed by SSPC-SP 11.

(a) SSPC-VIS 1, "Guide and Reference Photographs for Steel Surfaces Prepared by Dry Abrasive Blast Cleaning" is the most commonly used standard for evaluating the cleanliness of a prepared surface. The use of these standards requires a determination of the extent of rust on the uncleaned steel; this is graded from A to D. (b) SSPC-VIS 3, "Visual Standard for Power- and Hand-Tool Cleaned Steel." (c) SSPC-VIS 4/NACE VIS 7, "Guide and Reference Photographs for Steel Surfaces Prepared by Waterjetting." (d) SSPC-VIS 5/NACE VIS 9, "Guide and Reference Photographs for Steel Surfaces Prepared by Wet Abrasive Blast Cleaning"

types of self-curing and postcuring primers. The binder serves as a strong, adherent matrix for the zinc metal. The zinc dust must be present in sufficient amounts to provide metal-to-metal contact between both the zinc particles and the steel surface. The zinc dust provides protection to the steel substrate in the same manner as in galvanizing. If a break develops in the coating, the zinc acts as a sacrificial anode and corrodes preferentially; this provides protection of the iron for long periods. Laboratory tests and field experience indicate that inorganic zinc-rich primers can at least double the life of a coating system and can often increase it tenfold. To be effective, however, inorganic zinc-rich primers must be applied to a clean surface.

Organic zinc-rich primers are alternatives to the inorganic zinc-rich coatings when conditions are not appropriate for inorganic zinc-rich coatings. Organic zinc-rich primers can be formulated with epoxy, urethane, vinyl, and chlorinated rubber binders. The most common binder used for marine applications is polyamide epoxy. Zinc-rich epoxies provide a lower degree of conductivity and cathodic protection than inorganic zinc, but impart several other desirable characteristics:

- Organic zinc-rich primers frequently may be applied over old paint, which makes them a good choice for maintenance painting.
- The good adhesion of the epoxy binder makes surface preparation requirements less stringent than those for inorganic zinc-rich coatings. Near-white metal surfaces are adequate for offshore applications, and commercial grade grit blasting can be used in less severe environments.
- The epoxy binder provides some protection to the zinc, and this allows moderate exposure of

the primer to the marine environment without corrosion of the zinc and formation of zinc corrosion products. Zinc corrosion products can cause intercoat adhesion problems and paint blistering.

Topcoats

Topcoats for steel serve mainly to protect the primer and to add color and appearance. To serve this function, they must be:

- Barrier coatings impervious to moisture, salt, chemicals, solvents, and ion passage
- Strong and resistant to mechanical damage
- Of adequate color and gloss retention

Some of the most common topcoats in use are discussed below, and detailed information on each of these types is available in the article "Organic Coatings and Linings" in Volume 13A of the *ASM Handbook*.

Alkyds are the most common and versatile coatings in existence, but they are seldom used in severe marine applications, because of their poor performance over steel. This poor performance is due to the oil base of the alkyd. As corrosion proceeds on steel, hydroxyl ions (OH^-) are generated at cathode sites. Hydroxyl ions saponify (break down) the oils in the coating, and this results in coating failure.

Alkyds are the product of the reaction of a polybasic acid, a polyhydric alcohol, and a monobasic acid or oil. The number of possible combinations is large; therefore, a wide range of performance is available. Alkyds are used in marine service in relatively mild applications, such as interior coatings for cabins, quarters, engine rooms, kitchens, heads, and some superstructure applications.

Vinyls also have a broad range of desirable properties. Most vinyl resins are the product of the polymerization of polyvinyl chloride (PVC) and polyvinyl acetate (PVA). Vinyls are solvent-base coatings that form a tight homogeneous film over the substrate. They are easy to apply by brush, roller, and spray. Intercoat adhesion is excellent because of the solvent-base nature of the coating. Vinyls do not oxidize or age, and they are inert to acid, alkali, water, cement, and alcohol. They do soften slightly when covered with some crude oils. Vinyl coatings dry quickly and can be recoated in a short time (often in minutes), depending on the solvent used. Vinyl coatings are also flexible and can accommodate the motion of the steel beneath them, such as when a ship or platform is launched.

Vinyls were extensively used on ships and offshore platforms for many years, and they are still in use in many areas. However, they have given way to epoxies in most marine applications because vinyl coatings are relatively thin and are not very strong. Film thickness is typically only 50 μm (2 mils) per coat, and the coatings cannot withstand mechanical abuse. In addition, vinyls are not very effective for covering rough, previously corroded surfaces.

Chlorinated rubber coatings are based on natural rubber that has been reacted with chlorine to give a hard, high-quality resin that is soluble in various solvents. Chlorinated rubbers have been used for many years as industrial-type paints because of their low moisture permeability, strength, resistance to ultraviolet (UV) degradation, and ease of application. Chlorinated rubbers have found application on ships and containers, railroads, and as traffic paint for road stripes. For many years, chlorinated rubber coatings were used to paint ships because of their ease of application and reparability, tolerance of poor

Table 2 Properties of abrasives

Abrasive	Moh's hardness	Shape	Bulk density		Color	Free silica, wt%	Degree of dusting	Reuse
			kg/m ³	lb/ft ³				
Naturally occurring abrasives								
Sand								
Silica	5	Rounded	1600	100	White	90+	High	Poor
Mineral	5–7	Rounded	2000	125	Variable	5	Medium	Good

surface preparation, fast drying characteristics, and relatively good wear and abrasion resistance. They are still used on ships and have been the standard paint system for containers. Modern fleet owners, however, have phased out chlorinated rubbers in favor of higher-quality coating systems, such as epoxy, for reasons to be discussed below.

Epoxyes. The combination of excellent adhesion (some can be applied underwater), good impact and abrasion resistance, high film builds (up to 6.4 mm, or 1/4 in., on a wet, vertical surface), relatively low cost, and excellent chemical and solvent resistance has made epoxy coatings the workhorses of modern marine coatings. These properties result in service lifetimes of 7 to 12 years on ships, offshore platforms, and coastal applications when epoxy topcoats are applied over inhibited epoxy or inorganic zinc-rich primers. Because epoxyes are chemically cured, a wide range of properties can be achieved by varying the molecular weight of the resin, the type of curing agent, and the type of pigments or fillers used.

Immersion Coatings

Immersion coatings for submerged marine service have far greater requirements than other organic coatings. They must resist moisture absorption, moisture transfer, and electroendosmosis (electrochemically induced diffusion of moisture through the coating). They also must be strong and have good adhesion.

Most ship hulls and many marine structures use cathodic protection to supplement the protection afforded by organic coatings (see the article "Marine Cathodic Protection" in this Volume). This is desirable because it is virtually impossible to apply and maintain a defect-free organic coating system on a large structure. When cathodic protection is used, the immersion coating must be able to resist the additional conditions imposed upon it by the cathodic potential (blistering) and resulting alkalinity (cathodic delamination).

Property Requirements

Barrier Properties. To be effective in seawater immersion service, an organic coating must have a low moisture vapor transfer rate as well as low moisture absorption. Moisture absorption is the molecular moisture absorbed

into and held within the molecular structure of the coating. This property is not important to the effectiveness of the coating unless the moisture absorption lowers the dielectric characteristics of the coating and increases the passage of electrical current. Moisture vapor transfer, on the other hand, is important, particularly when the coating is exposed to an external current (as in cathodic protection). Generally, the lower the moisture vapor transfer rate of a coating, the more effective the coating.

Where electroendosmosis may be encountered, adhesion is also very important. Most organic coatings are negatively charged, and under cathodic protection, the cathode has an excess of electrons, which makes it negatively charged. This being the case, coatings with a high moisture vapor transfer rate or questionable adhesion would be more subject to damage and blistering by cathodic potentials.

Mechanical Properties. Coatings used on marine structures must be strong. Most damage to marine coating systems is mechanical, not a breakdown of the coating from exposure to seawater. Immersion coatings must have good impact and abrasion resistance and must be able to flex well enough to maintain contact with the steel substrate when it is bent. Rubbing by mooring ropes, chains, and crane wire ropes, as well as impact from cargo handling, work parties, and berthing operations, are major causes of damage.

Types of Immersion Coatings

Many of the common paint formulations can be used for immersion service, but the most common coatings in use have been coal tar epoxyes and straight epoxyes. Restrictions are being imposed on coal tar materials leading to decreasing usage.

Coal tar epoxyes were introduced in 1955 and became the most common coatings in use on fixed marine structures (Ref 3). These thermosetting materials are available with a variety of setting temperatures and chemical curing systems. Coal tar epoxyes require near-white surface preparation and are very adherent and abrasion resistant. They tend to be brittle and should not be used on flexible structures.

Straight epoxyes (no coal tar) have been commercially available longer than coal tar epoxyes (Ref 4). Epoxyes are usually applied in thinner coats and are more expensive than coal tar epoxyes. Epoxyes have become the material of

choice for immersion service because of their superior performance (Ref 2, 4). They have replaced chlorinated rubbers for most ship hull applications, and they are available in a variety of polyamide- or amine-based formulations (Ref 3). Detailed information on these and other coating materials is available in the article "Organic Coatings and Linings" in Volume 13A of the *ASM Handbook*.

Antifouling Topcoats. Most shipboard applications require antifouling (AF) topcoats. The formulations for these coatings are changing because of environmental legislation. Historically, copper-containing AF coatings became standard, but had only a 12 to 18 month service life. These coatings were nearly replaced by organotin compounds, for example, TBT (tributyltin), before the environmental impact was understood. Copper-containing AF coatings are returning to higher-frequency use as conventional, ablative, and self-polishing types, the latter two offering the prospects of longer service lifetimes (Ref 5).

ACKNOWLEDGMENT

Marine Cathodic Protection

Robert H. Heidersbach, Dr. Rust, Inc.

James Brandt and David Johnson, Galvotec Corrosion Services

John S. Smart III, John S. Smart Consulting Engineers

CATHODIC PROTECTION (CP) is an electrochemical means of corrosion control that is widely used in the marine environment. A detailed explanation of the principles of CP appears in the article "Cathodic Protection" in *ASM Handbook*, Volume 13A, 2003.

Cathodic protection can be defined as a technique of reducing or eliminating the corrosion of a metal by making it the cathode of an electrochemical cell and passing sufficient current through it to reduce its corrosion rate. All CP systems require:

- Voltage
- Current
- Anode
- Cathode
- Return circuit
- Electrolyte

Two types of CP systems are: impressed-current (active) systems (ICCP) and sacrificial anode (passive) systems (SACP). Both are common in marine applications. In recent years, hybrid systems—combinations of impressed-current and sacrificial anodes—have been used for very large marine structures.

Cathodic Protection Criteria

A number of criteria are used to determine whether or not the CP of a structure is adequate. These criteria, covered in NACE RP0176 (Ref 1), include potential measurements, visual inspection, and test coupons.

Potential Measurements. Reference 2 specifies a negative (cathodic) voltage of at least -0.80 V between the platform structure and a silver-silver chloride (Ag/AgCl) reference electrode contacting the water. Normally, voltage is measured with the protective current applied. The -0.80 V standard includes the voltage drop across the steel/water interface, but does not include the voltage drop in the water.

Application of the protective current should produce a minimum negative (cathodic) voltage shift of 300 mV. The voltage shift is measured between the platform surface and a reference electrode contacting the water; it includes the

voltage drop across the steel/water interface but not the voltage drop in the water.

Visual inspection should indicate no progression of corrosion beyond limits acceptable for platform life (Ref 1).

Corrosion test coupons must indicate a corrosion type and rate that is within acceptable limits for the intended platform life (Ref 1).

A number of other criteria are used, but in practice, -0.80 V versus Ag/AgCl is the most common. Other reference electrodes that can be used for marine applications are listed in Table 1.

Anode Materials

The choice of anode material depends on whether active (ICCP) or passive (SACP) systems are under consideration. Sacrificial anodes must be naturally anodic to steel and must corrode reliably (avoid passivation) in the environment of interest. However, above all, sacrificial anodes should be inexpensive and durable. Impressed-current anodes rely on external voltage sources; therefore, they do not need to be naturally anodic to steel. They usually are cathodic to steel if not forced to assume anodic potentials by the impressed current. Additional information on materials for sacrificial and impressed-current anodes is available in the article "Cathodic Protection" in *ASM Handbook*, Volume 13A.

Sacrificial Anodes. Commercial sacrificial anodes are magnesium, aluminum, or zinc or their alloys. Table 2 lists the energy capabilities of sacrificial anode alloys. Magnesium anodes have not been popular for offshore applications since the 1980s because of improvements in aluminum and zinc anodes. Several operators

have experimented with composite sacrificial anode systems for offshore platforms. These designs use aluminum or zinc anodes for long-term performance and have magnesium anodes that are intended to provide an initially high current density and polarize the platform quickly to the desired protection potential. Results from the limited applications of this composite design are mixed, and this concept remains controversial.

Aluminum anodes (aluminum-zinc alloys) are the preferred sacrificial anodes for offshore platform cathodic protection. This is because aluminum anodes have reliable long-term performance when compared to magnesium, which may be consumed before the platform has served its useful life. Aluminum also has better current/weight characteristics than zinc. Weight can be a major consideration for large offshore platforms.

The major disadvantage of aluminum for some applications—for example, the protection of painted ship hulls—is that aluminum is too corrosion resistant in many environments. Aluminum alloys will not corrode reliably onshore or in freshwaters. In marine environments, the chloride content of seawater depassivates some aluminum alloys and allows them to perform reliably as anode materials. Unfortunately, it is necessary to add mercury, antimony, indium, tin, or similar metals to the aluminum alloy to ensure that this depassivation occurs. Heavy-metal pollution concerns have led to bans on the use of mercury alloys in most locations.

Aluminum-zinc-indium anodes have become the most popular choice for pipeline bracelets in seawater or seamud. The greater current capacity allows for much lighter weight anodes to be handled and installed. Additionally, although the

Table 2 Energy characteristics of materials used for sacrificial anodes

Material	Energy capability		Consumption rate	
	A · h/kg	A · h/lb	kg/A · yr	lb/A · yr
Al-Zn-In	2535–2601	1150–1180	3.5–3.4	7.6–7.4
Al-Zn-Hg	2750–2840	1250–1290	3.2–3.1	7.0–6.8
Al-Zn-Sn	925–2600	420–1180	3.4–9.4	7.4–20.8
Zinc	815	370	10.8	23.7
Magnesium	1100	500	7.9	17.5

alloy operates at a lower efficiency, it should be the only alloy used at temperatures above 60 °C (140 °F).

Zinc anodes are used on ship hulls because, unlike aluminum, zinc will continue to perform when ships enter the brackish water or freshwater of harbors. Tankers with combination ballast/product tanks use zinc anodes because of their lower tendency to cause sparks if they fall from their supports and strike steel.

Zinc bracelet anodes are also used on pipelines. Again, they would be the preferred choice in brackish or freshwater and bottom mud. Because large-diameter marine pipelines must be buoyancy compensated, the increased weight of zinc can be an advantage. Caution: zinc passivates above 60 °C (140 °F).

Sacrificial anode manufacturing tolerances are established for dimensions, weight, and condition.

Cracks or casting shrink tears in the body of an aluminum anode do not affect performance. Even with good foundry practices a certain amount of cracking will occur. Cracks are permitted within the body of the anode wholly supported by the core. These cannot exceed 5 mm (~0.2 in.) wide or be full circumferential. Individual owners typically specify their crack criteria, but in lieu of that, the recommendation is that no more than 10 cracks per anode is acceptable. Cracks less than 0.5 mm (~0.02 in.) wide are not counted. If cracks occur in a section of the anode that is not supported with a core, it is cause for rejection as this section of the anode may fall away if the cracking propagates. Additionally, longitudinal cracks are not permitted except in the final “topping-up” metal.

Weight. Anode net weight for large offshore anodes (over 50 kg or 110 lb) should be +3% for any one anode. The total order weight should not be more than +2% of the nominal order weight and not less than the nominal order weight.

Identification. Each anode should be stamped with a unique heat casting number to identify it with its laboratory test performance and other compliance data. Additionally, clients may wish to specify a casting sequence number and foundry identification stamp.

Dimensions. Each anode should be within +3% of the specified length or +25 mm (1 in.), whichever is less. The width should be within +5% of the nominal mean width and the depth should be within +10% of the nominal mean depth. The anode straightness should not deviate more than 2% of the nominal length from the longitudinal axis of the anode. To confirm compliance, typically 10% of the anodes should be inspected for dimensional compliance.

Anode cores on large offshore-type standoff anodes should be made from schedule 80 steel pipe with the diameter determined by the weight of the anodes cast on it. Typically 50 mm (2 in.) pipe cores are used on anodes from 100 to 200 kg (220 to 440 lb). Anodes from 200 to 300 kg (440 to 660 lb) should have 75 mm (3 in.) pipe cores and anodes over 300 kg should have anode cores

of 100 mm (4 in.) pipe. Flush-mounted anodes typically contain cores made from flatbar.

Impressed-Current Anodes. Most materials used as impressed-current anodes are insoluble and corrosion resistant, with very low rates of consumption (Table 3). Exchange current density—the ability of a material to sustain high current densities with lower power consumption—is an important consideration for some applications.

High-silicon cast iron is the most corrosion-resistant, nonprecious alloy in commercial use as an impressed-current anode. Anodes made with this alloy are very strong, durable, and abrasion resistant. The major disadvantage in offshore applications is the high weight/current characteristics of high-silicon cast iron. Marine applications for high-silicon cast iron anodes include docks and similar coastal structures.

Precious metals have the advantage of high exchange current densities (Ref 1). The practical result is that a small precious metal surface is equivalent to thousands of times the surface area of other anode materials. Therefore, a small surface of platinum or palladium may be more economical than a much larger anode of less expensive material. Early precious metal anodes were alloys that, after a short period of use, became enriched on the surface with the precious metal component. Anodes of this type are still used in harsh environments, such as Cook Inlet, Alaska, and the North Sea, where anode sleds weighing several tons are necessary to withstand high ocean currents and storm conditions. For most other applications, smaller anodes, consisting of precious metals clad to stronger substrates (for example, platinum bonded to a niobium substrate), have gained acceptance. The extreme weight advantages of these anodes over other systems make them especially desirable for deep-water structures.

Mixed-metal oxide anodes consist of a titanium substrate or core, manufactured to ASTM grade 1 or 2, whose surface is activated with an electrocatalyst of a proprietary mix of precious metal oxides, typically iridium, tantalum, or ruthenium. These anodes have gained acceptance for cathodic protection applications. Mixed-metal oxide anodes have many of the same advantages as precious metal anodes (light weight, high current capacity, and they can be used in all electrolytes).

Polymer Anodes. Several suppliers are marketing polymer anodes. These contain embedded

graphite conductors and are used in applications requiring low current densities, such as coastal concrete structures that use CP to reduce the corrosion of reinforcing steel. Most offshore applications require anodes with high current capacities so polymer anodes are not used.

Comparison of Impressed-Current and Sacrificial Anode Systems

Sacrificial anode cathodic protection systems are simpler than ICCP systems and require little or no maintenance except for periodic anode replacement. The capital cost of small systems is minimal, and they are often used for applications such as pipelines and boats. The capital cost of large systems is proportional to submerged surface area.

The capital costs of ICCP may be lower than those of SACP systems in applications such as large offshore platforms. Impressed-current systems are normally used where the low conductivity of the electrolyte (freshwater, concrete) makes sacrificial anodes impractical.

Cathodic Protection of Marine Pipelines

Corrosion control of marine pipelines is usually achieved through the use of protective coatings and supplemental CP. A variety of organic protective coatings can be used. They are usually applied in a factory so that the only field-applied coatings are at joints in pipeline sections. Larger marine pipelines have an outer “weight coating” of concrete. The CP system supplements these coatings and is intended to provide corrosion control at holidays (defects) in the protective coating.

Design Considerations. The average cathodic protection current density required to protect a marine pipeline will depend on the type of coating applied, the method used to coat field joints, the amount of damage inflicted on the coating during shipment and installation, whether or not burial is specified, and the location of the pipeline. Large-diameter pipelines can be protected by installing an ICCP system at one or both ends of the pipeline. Such a system would include a suitably sized transformer/rectifier unit and inert anodes, such as graphite or

Table 3 Typical current densities and consumption rates of materials used for impressed-current anodes

Material	Typical anode current density		Consumption rate	
	A/m ²	A/ft ²	kg/A · yr	lb/A · yr
Mixed-metal oxide	600	55.8	0.004	0.0088
Pb-6Sb-1Ag	160–215	15–20	0.045–0.09	0.1–0.2
Platinum (plated on substrate)	540–1080	50–100	6 × 10 ^{−6}	1.3 × 10 ^{−5}
Platinum (wire or clad)	1080–5400	100–500	10 ^{−5}	2.2 × 10 ^{−5}
Graphite	10.8–43	1–4	0.23–0.45	0.5–1.0
Fe-14Si-4Cr	10.8–43	1–4	0.23–0.45	0.5–1.0

high-silicon cast iron. Caution should be exercised to prevent overvoltage in seawater or marine mud.

Most marine pipelines are protected by the installation of bracelet-type zinc or aluminum alloy sacrificial anodes (Fig. 1). Electrical contact between the anode and the pipeline is made through an insulated copper cable bonded to the pipeline. Zinc anodes may either be high purity or alloyed. Aluminum anodes are usually fabricated from a proprietary Al-Zn-In alloy.

Design Procedures. Typically, bracelet anodes are spaced at a maximum of 150 m (500 ft) on small-diameter pipelines (<355 mm, or 14 in.) and 300 m (1000 ft) on larger pipelines. The current required for a segment of pipeline is calculated by using the current density required for the given environment, the surface area of the pipe segment, and the fraction of steel assumed to be bare. Anodes are then sized to fit the conditions; that is, the anode must have adequate weight to satisfy the relationship:

$$\frac{W}{C} > IL \quad (\text{Eq 1})$$

where W is the anode weight (kg), C is the alloy consumption rate in kilogram/amp year (kg/A yr), I is the anode current output (A), and L is the desired design life in years. The anode nominal current output must exceed the required current. Anode current output I is determined from Ohm's law:

$$I = \frac{E}{R} \quad (\text{Eq 2})$$

where E is the net driving voltage (V), and R is the anode-to-electrolyte resistance (Ω). Anode-to-electrolyte resistance R can be calculated

using an empirical relationship, such as McCoy's equation:

$$R = \frac{0.315\rho}{\sqrt{A}} \quad (\text{Eq 3})$$

where ρ is the electrolyte resistivity ($\Omega \cdot \text{cm}$), and A is the anode area (cm^2).

Data sheets from the manufacturer can also be consulted for information on the electrochemical properties of specific proprietary alloys. Anode geometry can be optimized by using a successive iteration technique, but most anode manufacturers offer a range of standard sizes, which can be optimized for specific applications. If the pipeline is to have a concrete weight coating for stabilization, the thickness of the anode should match the concrete thickness to facilitate installation. Anodes to be installed on nonweight-coated pipelines should have tapered ends so that the anodes do not hang up on the rollers of the lay barge.

Isolation. If the pipeline and the offshore production facilities are operated by separate parties, the pipeline is usually electrically isolated from the production facilities through the use of insulated flanges or monolithic isolation joints. This practice prevents loss of current from the pipeline cathodic protection system to the platform and facilitates recordkeeping. Pipelines are always electrically isolated from shore-based facilities, usually at the valve pit on the beach.

Cathodic Protection of Offshore Structures

Offshore oil production platforms are unusual because most platforms are not painted below the waterline. The cathodic protection system causes a pH shift in the water, which becomes more alkaline (higher pH). Most minerals are less soluble in alkalis than in near-neutral environments (neutral water has a pH of 7; the pH of seawater averages approximately 7.8). The higher pH near the cathode causes minerals to precipitate onto the steel surface and form a protective scale or calcareous deposit. Depending on such factors as water depth, temperature, and velocity, this protective scale may be calcium carbonate, magnesium hydroxide, or a mixture of these and other minerals.

The technology of offshore cathodic protection is rapidly changing. Many of these changes are required because offshore structures are now being built in deeper, colder water where mineral deposits are less likely to form. The formation of a mineral deposit in such conditions may require current densities as high as approximately 750 to 1000 mA/m² (70 to 93 mA/ft²).

Another problem associated with deep-water platforms is that current density requirements change with depth. In recent years, several deep-water platforms have been found to be underprotected. These North American platforms

(Gulf of Mexico and Santa Barbara Channel) were located in deep water, but the inadequate protection was at intermediate depths. Gases are more soluble at depth, and carbonate scales (calcareous deposits) are harder to deposit in deep, cold waters. This difficulty is offset by the fact that many deep waters have little dissolved oxygen and should therefore be less corrosive than shallow waters. It should be noted however, that Cook Inlet, the North Sea, and other stormy waters may be oxygen saturated (and presumably carbon dioxide saturated) all the way to the bottom.

Many operators prefer to use sacrificial anodes on offshore platforms because the SACP systems are simple and rugged. In addition, they become effective as soon as the platform is launched and do not depend on external electric power supplies. Surveys of the reliability of ICCP systems have led to the conclusion that they do not perform as well as sacrificial anode systems (Ref 3). Reasons for this lack of performance may be the poor or fragile design of some early impressed-current systems and the lack of ongoing maintenance.

Unfortunately, the weight of sacrificial anodes can be a serious consideration for deep-water platforms. Impressed-current systems are gaining acceptance. Some operators have introduced hybrid designs. In these designs, the primary cathodic protection system uses impressed current, and a sacrificial anode system is used to protect the platform after launching and before the electrical system on the platform becomes operational. The Murchison Platform has the most widely publicized hybrid cathodic protection system (Ref 4).

In the past, the inefficiencies associated with CP design were not serious. Water depths were shallow, and CaP systems were overdesigned to ensure satisfactory performance. This was justified based on economics. A typical CP system is only 1 to 2% of the total capital cost of a new platform, but a retrofit may cost as much as the platform itself. Early platforms in Cook Inlet and the North Sea were underdesigned, and the costs of retrofits led to the efforts that produced NACE RP0176 (Ref 1). Reference 5 and 6 detail some problems experienced with deep-water platforms.

Design Procedures. A typical cathodic protection design procedure for an offshore platform might consist of:

1. Selection of a proper maintenance current density; this will depend on the geographic location (see Table 4)
2. Calculation of surface areas of steel in mud and in seawater
3. Calculation of the total amount of anode material required to guarantee a desired life
4. Selection of an anode geometry. Initial current density for the Gulf of Mexico (calculated for a single anode from Dwight's equation; see the example below) should exceed 110 mA/m² (10 mA/ft²), assuming a native potential of 0.28 V between bare steel

Fig. 1 Typical pipeline bracelet anodes

and aluminum anodes. See Tables 4 and 5 for resistivity of seawater.

- Judicious distribution of anodes on the steel, assuming a throwing power of 7.6 m (25 ft) in line of sight and placing anodes within 3 m of all nodes

The criterion for complete cathodic protection is steel structure potential more negative than -0.80 V versus the Ag/AgCl reference electrode at any point on the structure.

Example 1: Sacrificial Anode Calculation.

This is a typical method for calculation of galvanic anode current output and anodes required using initial, maintenance, and final current densities. This method has been commonly employed in the past for CP design, so practitioners tend to be familiar with it.

For a platform in the Gulf of Mexico, the number of anodes required for protection must satisfy three different calculations. There must be enough anodes to polarize the structure initially (initial current density I_{prot} from Table 4), to produce the appropriate current over the design life of the structure (mean current requirement, \bar{I}), and to produce enough current to maintain protection at the end of the 20 year design life (final current requirement, I_{prot20}). Assume that structure surface area needing protection is 3111 m^2 ($33,484 \text{ ft}^2$) in water (A_w), 4458 m^2 ($47,984 \text{ ft}^2$) in mud (A_m); ρ is $20 \Omega \cdot \text{cm}$ (Table 4).

From a modification of Dwight's equation, the resistance of a cylindrically shaped anode to the electrolyte in which it is placed is equal to the product of the specific resistivity of the electrolyte and certain factors relating to the shape of the anode:

$$R = \frac{\rho K}{L} \left[\ln \frac{4L}{r} - 1 \right] \quad (\text{Eq 4})$$

where R is anode-to-electrolyte resistance (Ω), ρ is electrolyte resistivity ($\Omega \cdot \text{cm}$) (see Table 4), K is 0.159 if L and r are cm, or 0.0627 if L and r are in., L is length of anode cm (in.), r is radius of anode cm (in.). For clarity, this example will be done in metric units. In this case, an anode with a square cross section (sides 21.6 cm) is being used, L is 274 cm, and mass per anode W is 330 kg.

For other than cylindrical shapes, $r = C/2\pi$, where C is cross-section perimeter. Thus, C is 86.4 cm and r is 13.7 cm. Based on this information, an anode made of an Al-Zn-In alloy is selected. This provides 0.28 V driving voltage between an aluminum-zinc anode of -1.08 V (Ag/AgCl in seawater reference) and polarized steel.

Substituting into Eq 4, the resistance is:

$$R = \frac{(20)(0.159)}{274} \left[\ln \frac{4 \times 274}{13.7} - 1 \right] = 0.0392 \Omega$$

To determine the current output from an anode, use Ohm's law:

$$I = \frac{E}{R}$$

$$I = \frac{0.28}{0.0392} = 7.14 \text{ A/anode} \quad (\text{Eq 5})$$

The number of anodes (N) required for initial protection is:

$$N = \frac{I_{\text{prot}} \cdot A_w + I_{\text{protmud}} \cdot A_m}{I}$$

$$= \frac{(0.11 \text{ A/m}^2)(3111 \text{ m}^2) + (0.0215 \text{ A/m}^2)(4458 \text{ m}^2)}{7.14 \text{ A}}$$

$$= 61 \quad (\text{Eq 6})$$

I_{prot} and I_{protmud} are the initial current densities from Table 4.

In order to meet the mean current (\bar{I}) requirements, the weight loss of anodes over the 20 year design life is calculated based on the consumption rate (CR) given in Table 2.

$$\bar{I} = \bar{I}_w \cdot A_w + \bar{I}_m \cdot A_m$$

$$= (55 \text{ mA/m}^2)(3111 \text{ m}^2)$$

$$+ (10.8 \text{ mA/m}^2)(4458 \text{ m}^2) = 219 \text{ A} \quad (\text{Eq 7})$$

Using CR 3.5 kg/A · yr:

$$W = (3.5 \text{ kg/A} \cdot \text{yr})(219 \text{ A})(20 \text{ yr}) = 15,330 \text{ kg}$$

The number of anodes (without considering efficiency and utilization) is:

$$N = \frac{15,330 \text{ kg}}{330 \text{ kg/anode}} = 46$$

Finally, to verify that sufficient protection is maintained at the end of the 20 year design life, a calculation is made similar to the initial current calculation, except with the reduced anode dimension that represents the anode at the end of its life. This anode design initially had an effective radius (r_i) of 13.7 cm (5.41 in.). There is an inert core with a radius (r_c) of 5.7 cm (2.25 in.). The effective (end-of-life) dimension (r_e) is:

$$r_e = r_i - (r_i - r_c) \times 0.9$$

$$= 13.7 - (13.7 - 5.7) \times 0.9$$

$$= 6.5 \text{ cm} \quad (\text{Eq 8})$$

where 0.9 is a utilization factor for a standoff anode. Assuming there is no change in anode length, the final current output per anode is:

$$I = \frac{E}{R_f}$$

$$R_f = \frac{(20)(0.159)}{(274)} \left[\ln \frac{4 \times 274}{6.5} - 1 \right]$$

$$= 0.0479 \Omega$$

$$I = \frac{0.28 \text{ V}}{0.0479 \Omega} = 5.85 \text{ A} \quad (\text{Eq 9})$$

Table 4 Design criteria for cathodic protection systems

Production area	Environmental factors (a)				Typical design current density(d), mA/m ² (mA/ft ²)

(a) Typical values and ratings based on average conditions, remote from river discharge. (b) Water resistivities are a function of both chlorinity and temperature. See Table 5. (c) In ordinary seawater, a current density less than the design value suffices to hold the structure at protective potential once polarization has been accomplished and calcareous coatings are built up by the design current density. *Caution:* Depolarization can result from storm action. (d) Conditions in the North Sea can vary greatly from the northern to the southern area, from winter to summer, and during storm periods. (e) Initial current densities are calculated using Ohm's Law and a resistance equation, with the original dimensions of the anode. See example of this calculation, which uses an assumed cathode potential of -0.80 V (Ag/AgCl [seawater]). (f) Mean current densities are used to calculate the total weight of anodes required to maintain the protective current to the structure over the design life. See example. (g) Final current densities are calculated in a manner similar to the initial current density, except that the depleted anode dimensions are used. See example.

Table 5 Resistivity

Chlorinity(a), ppt	Resistivity $\Omega \cdot \text{cm}$					
	at 0 $^{\circ}\text{C}$ (32 $^{\circ}\text{F}$)	at 5 $^{\circ}\text{C}$ (41 $^{\circ}\text{F}$)	at 10 $^{\circ}\text{C}$ (50 $^{\circ}\text{F}$)	at 15 $^{\circ}\text{C}$ (59 $^{\circ}\text{F}$)	at 20 $^{\circ}\text{C}$ (68 $^{\circ}\text{F}$)	at 25 $^{\circ}\text{C}$ (77 $^{\circ}\text{F}$)
19	35.1	30.4	26.7	23.7	21.3	19.2
20	33.5	29.0	25.5	22.7	20.3	18.3

(a) ppt, part per trillion.

The anodes required are:

$$N = \frac{I_{\text{prot20}} \cdot A_w + I_{\text{protmud20}} \cdot A_m}{I}$$

$$= \frac{(0.075 \text{ A/m}^2)(3111 \text{ m}^2) + (0.01076 \text{ A/m}^2)(4458 \text{ m}^2)}{5.85}$$

$$= 48$$

(Eq 10)

where the final current densities are from Table 4. For this application, 61 anodes are needed for initial protection, 46 are required for mean current density, and 48 are required at end-of-life. The proper number to use is 61.

Dwight's equation is valid for long cylindrical anodes when $4L/r \geq 16$. For anodes when $4L/r < 16$ or for anodes that do not approximate cylindrical shapes, equations such as Crennell's/McCoy's (Eq 3) or other versions of Dwight's may better predict the actual current output of the anodes. Theoretically, for a deep-sea submerged cylindrical anode, a more accurate equation would be as shown in Eq 11; however, Eq 4 is more widely used in CP practice.

$$R = \rho \frac{K}{L} \left[\ln \left(\frac{2L}{r} \right) - 1 \right] \quad (\text{Eq 11})$$

Note:

- For practical designs and to ensure adequate current to protect the structure during the life of the anode, the length (L) and radius (r) should be selected to show the condition of the anode when it is nearly consumed. For an elongated anode, the change in length may be ignored.
- If the structure potential rises above the minimum protection potential of -0.80 volt ($\text{Ag}/\text{AgCl}/\text{seawater}$), E becomes less than 0.25 V. This decreases the anode current output and increases anode life.
- The anode net weight must be sufficient to provide the calculated current for the design life of the system, in accordance with the actual consumption rate of the anode material selected (Table 2).

Anode Distribution. A final consideration concerns the positioning of anodes about the structure. They are placed within 3 m (10 ft) of nodes (welded or cast locations with the highest structural loading), but elsewhere are assumed to protect steel in line of sight within a 7.6 m (25 ft) radius. Thus, areas shadowed by other structural elements may not be fully protected by any particular anode.

Computer-aided cathodic protection designs for offshore structures have been used by several organizations since the 1980s. These computer-aided designs are of two types. Computers have been used to make calculations such as wetted surface area versus anode consumption that are commonly needed for CP design. The computer is a time saver that allows a greater number of alternatives to be considered, but does not change the actual methodology of design.

An alternative approach is to use numerical techniques, such as finite element, finite difference, or boundary integral, to model the potential-current distribution field in the region of an offshore structure. Computers can be programmed to generate complex analyses of various alternative designs (Ref 7). In the past, these computerized designs had limited acceptance because of the expense associated with the inputting designs and the time delay caused by communications difficulties among the operator, the cathodic protection designer, and the computer expert. The increased memory capabilities of personal computers now allow these numerical programs to be run on them. Design engineers are now able to compare a number of design alternatives quickly and inexpensively. The same modeling techniques—finite element, finite difference, and boundary integral—that are used for structural design can be used for cathodic protection design (Ref 7–12). Figure 2 is a typical computer-generated plot of potential gradients around a node on an offshore platform. Comparisons of plots generated using different anode locations allow engineers to quickly determine the optimal locations for any portion of the platform. Color coding on the monitor display allows the engineer to identify quickly locations where additional CP current is needed.

Cathodic Protection of Ship Hulls

Ships normally have protective coatings as their primary means of corrosion control. Cathodic protection systems are then sized so that an adequate electric current will be delivered to polarize the structure to the desired level. This is done for new structures by estimating the percentage of bare steel that results from holidays in the protective coatings. Once the estimated amount of bare steel is determined, anodes are sized to provide adequate current densities for the design life of the system.

Fig. 2 Computer-generated plot of potential gradient distribution at the node of an offshore platform support structure

Ships are returned to drydocks; so the size (and weight) of anodes can be reduced from what would be necessary for permanent anodes on offshore pipelines or platforms since the anodes can be replaced. Anodes are concentrated near the bow and stern, where coating damage is most likely to occur. The stern is also the location where galvanic couples (for example, propeller to hull) are possible. Relatively small anodes are placed on ships in these locations. Small anodes are desirable to minimize the drag effects caused by turbulence due to anode protrusions.

Anode Materials. Aluminum anodes are available for ship hulls, but they can passivate and become inactive on ships that enter rivers or brackish estuaries. For this reason, zinc anodes are almost universally used in commercial service.

Impressed-current cathodic protection systems are used on very large ships. The galvanic couple between the propeller, the shaft, and the hull of the ship can cause significant corrosion problems. Modeling of the current requirements for cathodic protection near tanker propellers was one of the first applications of the computer in cathodic protection design (Ref 11, 12).

Impressed-current cathodic protection systems can produce overprotection in some cases. Organic coatings can disbond because of the formation of hydrogen gas bubbles underneath coatings. Coating disbondment can produce increased surface areas that require more cathodic protection and is controlled by placing dielectric shields between the impressed-current anode and the hull. Larger shields are sometimes fabricated from glass-reinforced epoxy, which is molded directly on the hull of the ship. At one time, coating disbondment was a major concern, but modern coatings are resistant to disbonding. Hydrogen embrittlement of steel due to cathodic protection is sometimes a concern. This has been a problem on case-hardened shafts, bolts, and other high-strength attachments. Most structural steels have relatively low strength as well as minimum susceptibility to hydrogen embrittlement.

External Corrosion Direct Assessment Integrated with Integrity Management

Joseph Pikas, MATCOR Inc.

EXTERNAL CORROSION DIRECT ASSESSMENT (ECDA) is a structured process intended for use by pipeline operators to assess and manage the impact of external corrosion on the integrity of underground pipelines. The process integrates field measurements with the physical characteristics, environmental factors, and operating history of a pipeline. ECDA includes primarily nonintrusive or above ground examinations, which are tailored to the pipeline or segment to be evaluated. In addition, physical examinations (direct assessments) of the pipeline at sites identified as potential areas of concern by analysis of the indirect examinations are included. A detailed description of the ECDA process is given in the NACE International standard (Ref 1).

ECDA represents a way to control integrity-related threats through a structured process while maintaining reasonable operating and maintenance costs. A pipeline vulnerable to multiple threats from external corrosion or third party intrusions (mechanical damage) may require direct assessment. One major factor in the control of costs is the proper selection and matching of tools and processes to the predetermined threats. ECDA is a continuous improvement process through the use of successive applications. An operator using established criteria can track the reliability of results when the ECDA process is applied. The effectiveness of this process is measured by being able to address with confidence the anomaly locations of concern, and by having a safe operating pipeline system. In the United States, pipeline systems are governed by the Office of Pipeline Safety (OPS) in accordance with integrity management rules.

Four Step ECDA Process

ECDA is a four step process that integrates data and information from pipeline, construction, and cathodic protection records, physical pipe examinations along the pipeline, and operating history. Through successive application of the four step process, a pipeline operator

can identify and address where corrosion activity has occurred, is occurring, or may occur. Results from ECDA are used to prioritize future integrity-related actions. The four steps are:

1. *Preassessment*: Collects historic and current data to determine if ECDA is feasible, defines ECDA regions, and selects indirect inspection tools.
2. *Indirect examinations*: Conducts above ground inspection(s) to identify and define coating faults, anomalies, and corrosion activity.
3. *Direct examinations*: Evaluates indirect inspection data to select sites and then conducts excavations for pipe examinations.
4. *Postassessment*: Analyzes data collected from the previous three steps to assess the effectiveness of the ECDA process and determine re-assessment intervals. ECDA has a proactive advantage over alternative integrity assessment methodologies, such as pressure testing and in-line inspection, by identifying areas where defects could become an integrity concern in the future.

Pipeline Integrity and Data. The ECDA process requires that integrity and operating history data are integrated with data from indirect and direct examinations. This is a strength of the ECDA process. Analyzed together, the data can provide a required integrity confidence level or lead to recommendations for further action, such as additional field testing, in-line inspection runs (smart pigging), hydrostatic testing, reconditioning, or pipe replacement.

Although the focus of ECDA is to locate external corrosion, it is recognized that other conditions that adversely impact pipe integrity may be associated with coating faults. Such conditions should be addressed using appropriate remediation criteria covered in company operating procedures, or other industry documents such as ASME B31.8S (Ref 2) and API 1160 (Ref 3). External corrosion is only one of 22 threats (Ref 4) that can impact structural integrity. Therefore, ECDA only addresses part of an operator's overall integrity management program. Overall integrity should be established

by considering all credible threats that can impact the pipeline or segment being evaluated.

Direct bell hole examination (direct visual examination of the pipe or coating) is used to prioritize corrosion defects for remediation and post-assessment determination of pipeline integrity and the safe operating pressure for a specified time interval. As digging is expensive, ECDA can improve location selection by integrating results from preliminary integrity analyses, statistical data analyses, and inferential measurements.

ECDA should be used for below-ground sections of transmission and distribution piping systems constructed from ferrous materials. It may be used in conjunction with or in place of other integrity assessment tools including in-line inspection, pressure testing, or other proven technology. The ECDA process applies to coated as well as bare pipe; however, all inspection methods do not apply to both coated and bare pipe and may require different interpretation based upon the particular application.

Step 1: Preassessment (Assessment of Risk and Threats)

The preassessment action step consists of the collection, analyses, and review of pipeline data to determine if the ECDA process can be applied over the pipeline or a segment of the pipeline.

ECDA specific data analysis includes many of the same data elements that are typically considered in the overall pipeline risk (threat) assessment. Depending on the operator's integrity management plan, operating and maintenance procedures, and ECDA data, analyses could also be performed in concert with a general risk/threat assessment effort.

Data elements are grouped into five categories as shown below. These data have been selected to provide for a comprehensive analysis and guidance for establishing ECDA feasibility and regions. A data table should contain these essential data elements, but additional elements may also be utilized. (Ref 1 provides guidance

for the use of each element and its influence on the ECDA process in its first table). The five categories to be included in the analysis process are:

- *Pipe related:* such as wall thickness, diameter, specified minimum yield strength (SMYS), year of manufacture
- *Construction related:* such as year of installation, installation design and practices, depth of cover
- *Soils and other environmental factors:* such as soil type, drainage, topography
- *Cathodic protection (CP):* including CP type, test points, maintenance, coating
- *Pipeline operations:* including operating temperature, monitoring, excavation results

The preassessment determines if conditions exist where particular ECDA methods cannot be used or where ECDA is totally precluded. Analyses can also be used to estimate the likelihood and extent of existing corrosion and prioritize indirect assessment steps. Where ECDA feasibility cannot be established, analyses results can be used as guidance for selecting alternative integrity assessment methods.

One of the major objectives derived from collecting the data elements is to assist in determining if ECDA tools are applicable for determining pipeline integrity at locations where external corrosion has been determined to be a credible threat. Such a risk (or threat) assessment is required as an element of the integrity management plan. Risk/threat assessment is an accepted industry practice; it is a systematic method for integrating and using a variety of data elements that together provide an improved understanding of the nature and locations of risks along a pipeline or segment. Such models can also be used to prioritize the severity of risk. Risk is typically described as the product of the probability of failure (POF) and a measure of the consequence of failure (COF).

Data collected for ECDA applicability analyses in the preassessment step can be analyzed using similar models without necessarily including the COF term used for risk assessment. This may include one general model or several specific models such as for soils or corrosion. In any case, the methods used for such analyses must be consistently and systematically conducted to permit an accurate assessment of ECDA feasibility, selection of ECDA regions, and determining the appropriate methods to be used in each region. These analysis results can also be the basis for prioritization based on the estimated corrosion severity and extent at each location. Depending on the integrity management plan and risk assessment methods used by individual pipeline operators, ECDA specific data analyses can be accomplished as a subset of the overall pipeline risk assessment.

Tools are selected based on their ability to detect corrosion activity and/or coating holidays under normal pipeline conditions. Reference 1 provides an ECDA selection matrix to determine the tool choices similar to Table 1.

The data is used to define ECDA regions along the pipeline. An ECDA region is a section (or sections) of a pipeline determined with reference to the ECDA tool selection matrix (Table 1). A section is suitable for the successful application of the same two above ground indirect examination methods. Other ECDA regions must be defined where data analyses and Table 1 indicate that different pairs of ECDA methods are needed.

ECDA regions only apply to selection of indirect examination methods.

Figure 1 provides an example of the definitions for ECDA regions. The pipeline operator must consider whether more than two indirect inspection tools are needed to detect corrosion activity reliably. The pipeline operator should consider all conditions that could significantly affect external corrosion where defining criteria

Table 1 ECDA tool selection matrix

Condition	Applicability(a)				
	Close interval survey (CIS)	Direct current voltage gradient (DCVG)	Alternating current voltage gradient (ACVG)	Soil contact with pipe locator (Pearson)	Pipeline current mapper (PCM)
Coating holidays	2	1, 2	1, 2	2	2
Anodic zones on bare pipe	2	NA	NA	NA	NA
Near river or water crossing	2	NA	NA	NA	2
Under frozen ground	NA	NA	NA	NA	2
Stray currents	2	1, 2	1, 2	2	2
Shielded corrosion activity(b)	NA	NA	NA	NA	NA
Adjacent metallic structures	2	1, 2	1, 2	NA	2
Near parallel pipelines	2	1, 2	1, 2	NA	2
Under high voltage AC transmission lines	2	1, 2	1, 2	2	NA
Shorted casing	2	1, 2	1, 2	2	2
Under paved roads(c)	2	1, 2	1, 2	2	2
Uncased crossing	2	1, 2	1, 2	2	2
Cased crossing	NA	NA	NA	NA	2
At deep burial locations(d)	2	1, 2	1, 2	2	2
Wetlands	2	1, 2	1, 2	2	2
Rocky terrain, rock ledges, rock backfill	NA	NA	NA	NA	2

(a) 1, applicable for small isolated coating holidays, typically < 6.5 cm² (1 in.²), and conditions that do not cause fluctuations in CP potentials under normal operating conditions. 2, applicable for large isolated or continuous coating holidays, or conditions that cause fluctuations in CP potentials under normal operating conditions. NA, not applicable without additional considerations. (b) An orifice through the soil is required. (c) Drilled holes required for paved areas. (d) All instruments lose sensitivity. Source: Ref 1

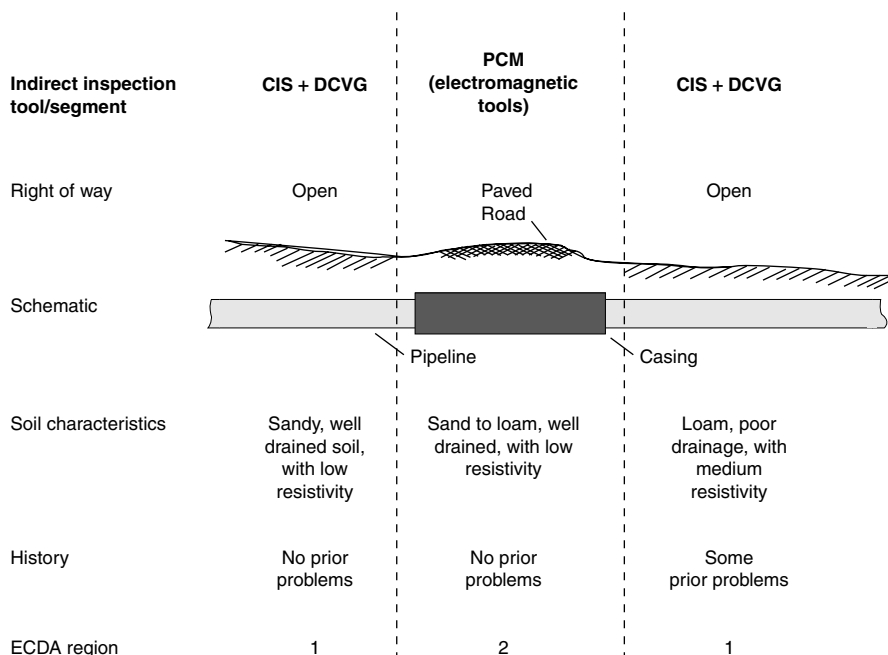

Fig. 1 Characteristics of external corrosion direct assessment (ECDA) regions. Inspect tool/segments: close interval survey, CIS; direct current voltage gradient, DCVG; pipeline current mapper, PCM

for ECDA regions. A single ECDA region does not need to be continuous. It can be broken along the pipeline, for example across rivers, paved roads, or parking lots.

The Fig. 1 example is a pipeline segment that indicated reasonably consistent conditions except that part of the segment has been paved so two regions are required with different measurement techniques.

The definitions of ECDA regions may be modified based on results from the indirect examination step and the direct examination step. The definitions made at this point are preliminary and are expected to be fine-tuned later in the total ECDA process. Once the ECDA regions have been defined, the operator should select a minimum of two indirect examination methods for each defined ECDA region. Depending on the specific conditions in an ECDA region as indicated by data analysis or sections of special concern, additional indirect examination methods may be required to achieve an adequate inspection reliability and/or resolve unexplained differences detected when comparing results from the two required indirect examinations. If the conditions determined by data analysis in a particular ECDA region are such that only one indirect examination method is applicable, ECDA methods should not be allowed and alternative in-line inspection (ILI), hydrostatic testing, or other proven methods must be used.

Demonstration of Feasibility. Under the OPS of the U.S. Department of Transportation, Gas Pipeline Integrity Rules, a pipeline operator must assess, analyze, and prove the conditions that allow ECDA. The pipeline integrity rule requires pipeline operators to develop an integrity management program for gas transmission pipelines located where a leak or rupture could do the most harm, called high consequence areas (HCAs). The rule requires pipeline operators to perform ongoing assessments of pipeline integrity, to improve data collection, integration, and analysis, to repair and remediate the pipeline as necessary, and to implement preventive and mitigation actions.

Conditions that require operator assessment are customer interruption or pipelines operating below a prescribed value of percent specified minimum yield strength (SMYS). Application of integrity data management systems and risk/threat assessment methodologies represent various approaches available to operators in order to fulfill the requirements for the direct assessment (DA) process. The Gas Pipeline Rule allows the use of DA methodologies for assessment of third party damage (this is mechanical damage that has occurred with coating damage) as long as it is used in its entirety, can demonstrate effectiveness, and is documented with the following auditable steps:

- Methods and procedures used to establish ECDA feasibility
- Methods for ECDA region establishment and region definitions

- Data analyses and integration methods including any models used
- Results of general risk (threat) analyses establishing the areas where external corrosion is a credible threat in HCAs

Step 2: Indirect Examinations

The second ECDA process step includes above-ground, indirect examinations in each ECDA region established in the preassessment step and analysis of the data. Depending on the indirect examination results and their consistency, these data analyses may indicate the need for additional indirect or preliminary direct examinations. An indirect examination process includes a feedback loop to facilitate continuous improvement of the preassessment step.

Prior to conducting indirect examinations, the extent of each ECDA region must be identified and clearly marked. Measures must be used to assure a continuous indirect examination is achieved over the pipeline or segment being evaluated. This could include some examination overlap into adjacent ECDA regions.

Indirect examinations should be conducted using closely spaced intervals and no greater than a 90-day time interval with a detailed assessment of the area. Each indirect examination must be conducted and analyzed in accordance with industry and NACE accepted practices.

Two indirect examinations should be conducted over the entire length of each ECDA region or HCA in the segment being evaluated. Results from these inspections are then evaluated to establish that these results are complementary. When analyzing indirect examination results, the operator must be aware that some spatial error will likely be present when comparisons are made. Errors can cause difficulties when determining the similarity between two indirect examination results. This can occur due to location differences at the ground surface when conducting the indirect examinations or changes in burial depth. Such error may be reduced by using an increased number of above-ground reference points such as fixed pipeline features and additional above-ground markers. Other techniques including commercially available software based graphical overlay methods may also be used to resolve spatial errors.

Depending on the particular indirect examination method used, the operator should also attempt to determine if the areas that may contain corrosion are active or inactive.

All indirect examination actions should be thoroughly documented. This may include the following:

- Indirect location identification versus the actual condition as indicated by any preliminary direct examinations
- Analyses of indirect process effectiveness and any difficulties encountered

- Feedback to the preassessment stage for improvements, modifications
- ECDA region locations, boundaries for future reference
- Anomaly severity classification versus that determined by direct examinations as in Table 2

The anomaly classifications are:

- *Severe*: indications that the pipeline operator considers as having the highest likelihood of corrosion activity
- *Moderate*: indications that the pipeline operator considers as having possible or questionable corrosion activity
- *Minor*: indications that the pipeline operator considers inactive or as having the lowest likelihood of corrosion activity

Step 3: Direct Examination

Direct examination requires excavations to expose the pipe surface, metal-loss measurements, estimated corrosion growth rates, and measurement corrosion morphology at coating faults identified during indirect examination. The goal of these excavations is to collect enough information to characterize the external corrosion anomalies that may be present on the pipeline or segment being evaluated.

Excavations for direct examinations should be made at one or more locations from each ECDA region in which coating faults have been found. Where an extended length pipeline is included in a particular ECDA region, additional excavations must be considered. Excavations should be conducted based on the initial estimated severity and prioritization established during indirect examination with most severely corroded areas and active areas examined first. Additional severity prioritization should be also conducted during direct examination, which will provide validation data for the preassessment and indirect examination steps.

The ECDA process is primarily focused on external corrosion anomalies. However, it is recognized that other threats often associated with coating fault locations, such as mechanical damage and stress-corrosion cracking (SCC), may also be discovered during the direct examination step. The operator's pipeline risk (threat) assessment process will provide guidance as to the potential existence of anomalies other than external corrosion. The operator must address such anomalies based on criteria contained in the appropriate industry standards.

Data that should be acquired prior to and during each excavation and before any coating removal are:

- Pipe-to-soil potential
- Soil resistivity
- Soil sample collection
- Water sample collection
- Coating condition assessment

- Microbiological influenced corrosion (MIC) analysis
- Corrosion product analysis
- Photographic documentation

The following additional data should be acquired during each excavation after coating removal:

- Coating thickness
- Coating adhesion
- Pipe temperature under coating
- Coating condition (blisters, disbondment, etc.)
- Under-film liquid pH
- Corrosion sample analysis
- Coating backside contamination analysis

During pipe examination at locations determined by the severe indications as in Table 2, corrosion depth measurements and severity estimates should be made using ASME B31G (Ref 5) or remaining strength of corroded pipe calculations, RSTRENG software (Ref 6), are made to determine the integrity of the pipeline. Sufficient corrosion depth measurements should be made at each excavation to provide adequate data to make a statistically valid maximum depth estimate that exists in each ECDA region.

The pipeline operator must establish criteria for prioritizing the need for direct examination of each indication found during the indirect examination step. Prioritization is the process of estimating the need for direct examination of each indication based on the likelihood of current corrosion activity plus the extent and severity of previous corrosion. Different criteria may be required in different regions, as a function of the pipeline condition, age, history of cathodic protection, and location history.

The minimum number of prioritization levels is given in Table 3:

- *Immediate action required:* This priority category should include indicators that the pipeline operator considers to have ongoing corrosion activity and that, when coupled with prior corrosion, pose an immediate threat.

- *Scheduled action required:* This priority category should include indicators that the pipeline operator considers may have ongoing corrosion activity but that, when coupled with prior corrosion, do not pose an immediate threat.

- *Suitable for monitoring:* This priority category should include indicators that the pipeline operator considers inactive or as having the lowest likelihood of ongoing or prior corrosion activity.

Step 4: Post Assessment

Where the operator has measured corrosion rate data that is applicable to the ECDA region, such actual rates may be used for inspection interval determinations in the post assessment step.

As a minimum, soil resistivity may be used; however, more precise corrosion rate estimates can be obtained from other soil measurements in addition to resistivity.

If conditions exist that prevent a statistically valid sample from being obtained from a single ECDA region, data from excavations in other similar ECDA regions, as defined in the pre-assessment step, may be used. Alternatively, additional excavations may be performed to obtain the necessary data.

Post assessment sets re-inspection intervals, provides a validation check on the overall ECDA process, and provides performance measures for integrity management programs.

The first step in post assessment is to determine the remaining pipeline life from calculations of the possible corrosion defects at coating fault locations that were not subjected to direct examination. Operators will have mathematical models for life calculations. An estimate can be made of the remaining pipeline life using:

$$RL = \frac{0.85}{P} \left(\left(\frac{P_f}{SF_{DR}} - MAOP \right) \frac{t}{CR} \right)$$

where RL is remaining life (yr); P is applied pressure (psi); P_f is burst pressure calculated by RSTRENG (psi); SF_{DR} is design requirement safety factor; $MAOP$ is maximum allowable operating pressure (psi); 0.85 is a calibration factor; t is the wall thickness (in units compatible with CR); and CR is the corrosion growth rate per year.

This method of calculating expected remaining life is reasonably conservative for pipeline external corrosion. Where data is inadequate or deficient, the half life must be used as a default on the basis for repair and reassessment intervals.

If the half life is acceptable, one additional excavation is to be performed for validation purposes. This excavation is to be performed at the coating fault location that was estimated to contain the next most severe defect not previously subjected to direct examination. Corrosion severity at this location should be determined and compared with the maximum severity predicted during the direct examinations.

- If the actual corrosion defect severity is less than half of the maximum predicted severity, validation is completed.
- If the actual corrosion severity is between the maximum predicted severity and one half of the maximum predicted severity, double the predicted maximum severity and recalculate the half life.
- If the actual corrosion severity is greater than the maximum predicted severity, the ECDA process may not be appropriate and the operator must return to the preassessment stage.

ECDA validation may also be performed using historical data from prior excavations on the same pipeline. Prior excavation locations must be assessed to determine that they are equivalent to the ECDA region being considered and such a comparison is valid. If validity is established,

Table 2 Example of severity classification

Inspection classification			
Inspection tool	Severe indications	Moderate indications	Minor indications
CIS	Two or more of the following must exist: <ul style="list-style-type: none"> • OFF potential less than -850 mV • ON potential less than -850 mV • Reduced potentials shifted in a positive direction 	Two or more of the following must exist: <ul style="list-style-type: none"> • OFF potential less than -850 mV • ON potentials greater than -850 mV • Reduced ON potentials shifted in a positive direction 	Any of the following can exist: <ul style="list-style-type: none"> • OFF potential at or near -850 mV • ON potential above -850 mV • Single spikes • Saw tooth patterns in both ON and OFF • Step potential
PCM	Greater than 20% change in 100 ft	Between 10 to 20% change in 100 ft	Less than 10% change in 100 ft
DCVG	36 to 100% IR anodic/anodic	16 to 35% IR cathodic/anodic	1 to 15% IR cathodic/neutral cathodic/cathodic
ACVG	Greater than 90 dB	50 to 89 dB	Less than 50 dB

Table 3 Example of indirect inspection categorization indication table

Priority level	Indicators
Immediate action required	<ul style="list-style-type: none"> • Severe indications in close proximity regardless of prior corrosion • Individual severe indications or groups of moderate indications in regions of moderate prior corrosion • Moderate indications in regions of severe prior corrosion
Scheduled action required	<ul style="list-style-type: none"> • All remaining severe indications • All remaining moderate indications in regions of moderate prior corrosion • Groups of minor indications in regions of severe prior corrosion
Suitable for monitoring	<ul style="list-style-type: none"> • All remaining indications

then maximum corrosion depths may be estimated from the prior data.

The last step in the post assessment stage is to set reinspection intervals. Repair intervals must be based on the expected half-life calculation or an equivalent method. The half-life (default data deficient) or equivalent (proof) can be used to prorate the repair interval.

Close-Interval Survey Techniques

Drew Hevle, El Paso Corporation
Angel Kowalski, CC Technologies, Inc.

A CLOSE-INTERVAL SURVEY (CIS) is a series of structure-to-electrolyte direct current (dc) potential measurements performed at regular intervals for assessing the level of cathodic protection (CP) on pipelines and other buried or submerged metallic structures (Fig. 1). Within the industry, the terms close-interval survey (CIS) and close-interval potential survey (CIPS) are used interchangeably.

Types of CIS include:

- *On survey*, data collection with the CP systems in operation
- *Interrupted or on/off survey*, a survey with the CP current sources synchronously interrupted
- *Asynchronously interrupted survey*, a close-interval survey with the CP current sources interrupted asynchronously, using the waveform analyzer technique
- *Depolarized survey*, a close-interval survey with the CP current sources turned off for some time to allow the structure to depolarize
- *Native-state survey*, data collection prior to application of CP
- *Hybrid surveys*, close-interval surveys incorporating additional measurements such as lateral potentials, side-drain gradient measurements (intensive measurement surveys), or gradient measurements along the pipeline

The term CIS (or CIPS) does not refer to surveys such as cell-to-cell techniques used to evaluate the direction of current (hot-spot surveys, side-drain surveys) or the effectiveness of the coating (traditional direct current voltage gradient, DCVG).

Typical CIS graphs are shown for a fast-cycle interrupted survey combined with a depolarized survey to evaluate a minimum of 100 mV of cathodic polarization (Fig. 2) and a slow-cycle interrupted survey (Fig. 3). Close-interval survey is used to assess the performance and operation of a CP system in accordance with established industry criteria for CP such as those in NACE International Standard RP0169. The -850 mV criteria is indicated on Fig. 2 and 3.

Close-interval survey is one of the most versatile tools in the CP toolbox and, with new integrity assessment procedures, has become an integral part of pipeline integrity program.

See the article "External Corrosion Direct Assessment Integrated with Integrity Management" in this Volume.

Close-interval survey data interpretation provides additional benefits, including:

- Identifying areas of inadequate CP or excessive polarization
- Locating medium-to-large defects in coatings on existing pipelines
- Locating areas of stray-current pickup and discharge
- Identifying possible shorted casings
- Locating defective electrical isolation devices
- Detecting unintentional contact with other metallic structures
- Testing current demand and current distribution along a pipeline
- Locating possible high-pH SCC risk areas or as a component of a stress-corrosion cracking direct assessment (SCCDA)
- Locating and prioritizing areas of risk of external corrosion as part of an integrity-management program or as a component of an external corrosion direct assessment (ECDA)

Certain conditions can make the data from a CIS difficult or impossible to properly interpret or make the survey impractical to perform. Examples include areas of high contact resistance, such as pipe located under concrete or asphalt pavement, frozen ground, or very dry conditions. Contact resistance in paved areas may be reduced by drilling through the paving to permit electrode contact with the soil. Contact resistance in dry areas can be reduced by moistening the soil with water until the contact is adequate. Because this is often difficult or impractical, CIS should be scheduled, when possible, to avoid unfavorable seasons. Other impediments to close-interval survey are adjacent buried or submerged metallic structures, surface conditions limiting access to the electrolyte, backfill with significant rock content or rock ledges, gravel, and dry vegetation. Telluric (natural currents near the surface of the earth) or other dynamic stray currents and high levels of induced alternating current (ac) can introduce errors into the potential measurements. Pipelines buried very deep, such as horizontal directional

drill crossings under rivers and highways, do not allow a high-resolution survey. Pipelines with locations at which coatings cause electrical shielding do not allow valid potential measurements. Pipelines without electrical continuity, such as with some forms of mechanically coupled pipe, do not allow for close-interval surveys.

CIS Equipment

The equipment required to perform a CIS comprises:

- Voltmeter
- Reference electrode(s)
- Electrical connection to the pipeline

Figure 1 is a sketch of the equipment used in a CIS. Depending on the type of survey, additional equipment may be required, such as:

- Pipe locator
- Distance measuring device
- Data loggers
- Current interrupters
- Global positioning system (GPS) surveying equipment

Voltmeters. To determine a pipe-to-electrolyte potential value, a voltmeter must measure the potential drop across an external circuit resistance that varies depending on the type of environment. To compensate for these variable conditions, voltmeters must be built with high impedance or input resistance. Typical minimum input resistance is >20 M Ω . A higher external resistance requires a higher input resistance to maintain accuracy during measurements. Voltmeters with low internal resistance can cause significant errors when measuring pipe-to-soil potentials. Additional relevant characteristics of the voltmeter are range, resolution, and accuracy.

Reference Electrodes. The choice of reference electrodes is determined by the environment in which the electrode is placed. For onshore surveys the most commonly used is the copper/copper-sulfate electrode (CSE). Other electrodes such as the silver/silver-chloride and

zinc/zinc-sulfate are used in environments such as seawater. The reference electrode calibration must be checked before and during the CIS. A common calibration method consists of measuring the potential difference between the working reference electrodes and a master electrode; differences less than 5 mV are typically acceptable. A reference electrode that fails a calibration check must be replaced or repaired before future use.

Electrical Connection. To perform a CIS, the voltmeter must be connected to the reference electrode and to the structure being inspected. The use of wire reels (relatively heavy gage wire on reels) or disposable wire (lighter gage wire) is necessary to maintain electrical contact with the structure and the voltmeter. This connection is normally made at test stations. A low-resistance current path is needed to minimize voltage drops in the metallic circuit. It is also important that the wire is properly insulated to avoid direct contact between the metallic conductor and the electrolyte.

Pipeline Location. Visual identification of the pipeline by aboveground appurtenances, casing vents, or pipeline markers may or may not be sufficient for accurate location of the pipeline.

If visual identification does not provide accurate location of the pipeline, radio-frequency pipeline locators or other devices may be required. In congested pipeline rights-of-way, areas of deep cover, small diameter or poorly coated pipe, or areas of high ac background potentials, conductive location techniques, or other more accurate location techniques and equipment may be required.

Distance Measuring Device. When performing a CIS, it is important to register the location where the pipe-to-electrolyte potential was measured. This can be accomplished by determining the relative distance to an above-ground reference point (such as a test station, valve station, or road crossing) by chaining or using another distance measuring device. The use of the GPS equipment also allows recording of testing locations.

Current Interrupters. When an interrupted CIS is performed, the use of current interrupters is required. If more than one dc source is interrupted, the interrupters must be able to synchronize their interruption cycle so that they remain in the same state simultaneously.

Data Loggers. It is a common practice to use a field computer (data logger) with a built-

in voltmeter to capture the pipe-to-soil potentials during a CIS. A data logger can store a large amount of data, including structure-to-electrolyte potentials, state of CP current (on/off), distance or chainage, geographical location, field comments, waveforms, and additional measurements. When a data logger is used on an interrupted CIS, it must be capable of recording the on and instant-off potentials at the specified interruption cycle. Data acquisition software and/or hardware for interrupted CIS must be adjusted to avoid recording transient potentials produced by a "spike effect."

Data loggers placed at a fixed test station to record structure-to-electrolyte potentials, named stationary loggers, are installed to detect the presence of dynamic stray current and verify the correct operation of current interrupters.

Preparation

Presurvey activities are essential for obtaining reliable results on a CIS.

Review and Analyze System Information. This pipeline system or other underground structure information includes:

- Structure-related data (geographical location, depth of burial, electrolyte resistivity, coating type, alignment drawings, locations of water crossings, types of terrain, locations of high-voltage AC power transmission lines and dc rail systems)
- Cathodic protection operating system data, test stations, electrical bonds
- Foreign CP systems
- Foreign underground structures in proximity to pipeline
- AC mitigation systems
- Electrical isolation devices

Equipment Calibration. The voltmeter and reference electrodes must be calibrated before starting the survey and records of the calibration should be maintained for data validation purposes.

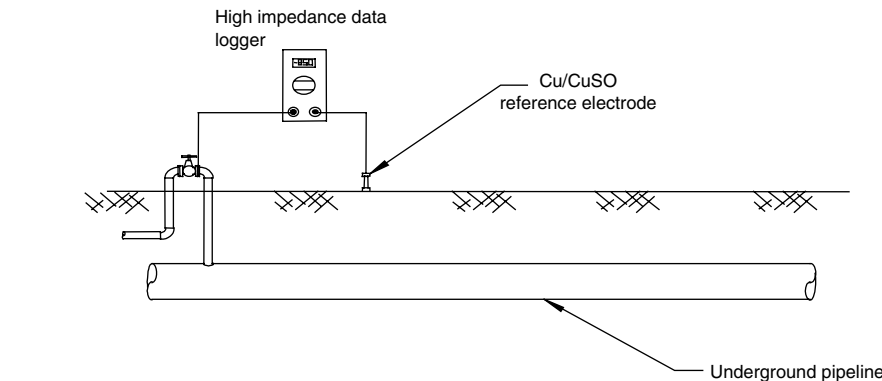

Fig. 1 Arrangement of close-interval survey components

Fig. 2 Typical graph of fast-cycle interrupted survey combined with depolarized survey. Distances are measured from a specified starting point, 123+00 is 12,300 ft.

Fig. 3 Typical graph of slow-cycle interrupted close-interval survey. Distances are measured from a specified starting point, 123+00 is 12,300 ft.

Direct Current Source Influence Test. If an interrupted CIS is performed, a dc source influence test must be performed at the different segments of the structure to be surveyed. This should be performed by interrupting all known dc sources individually and determining their coverage by measuring the potential difference between the on and the off portions of the interrupting cycle. The operating conditions of the dc sources should be measured and recorded. After the dc source influence test is completed, a dc source interruption plan can be elaborated for each section of the structure and the location of the stationary data loggers can be determined.

Locating Underground Structures. In order to perform the survey accurately, the precise location of the underground structure must be determined. Normally, the survey operator with the data logger either follows directly behind the pipe locator, or a separate locating crew marks the structure route at intervals of 15 to 30 m (50 to 100 ft).

Procedures

After completing the preparation activities the surveyor should define:

- Start and end points
- Survey direction
- Survey potential reading interval
- Aboveground reference features
- Precise location of the underground structure

If an interrupted survey will be performed, the surveyor should also define:

- dc interruption cycle
- dc interruption plan

The following activities should be performed during the execution of a CIS.

Install a Stationary Data Logger. For every section of the structure a stationary data logger may be located at a test station near the midpoint of the segment to be tested that day. This data logger is connected to the structure (test station) and to a reference electrode. The data logger will record structure-to-electrolyte potentials for the duration of the CIS. The data recorded should contain the date of the survey, the pipe-to-soil potential, and the time. Stationary data loggers are normally configured to capture a reading every second. These data allow the determination of possible dynamic stray currents and any depolarization that may affect the interpretation of the CIS results.

Structure-to-Electrolyte Potential Measurements. The surveyor will measure and record potentials at the defined interval and also record all relevant information about survey conditions. The distance and potential are the critical data; if time is also attached to each potential reading, these data can be compared with the data from the stationary data logger. Aboveground features may be recorded and referenced to start point of the survey to aid in relocation of indications.

The location of the electrical connection to the structure should be documented. External conditions such as changes in soil conditions, terrain, land use, and so forth should also be recorded. This information is valuable when analyzing the survey results. When performing an interrupted survey it is a good practice to periodically measure the waveform of the interrupted cycle to confirm the synchronization of the current interrupters.

End of Survey. When the surveyor arrives at the end point of the survey, additional measurements should be obtained, such as metal voltage (*IR*) drop, and, if performing an interrupted survey, the waveform of the interrupted cycle. The initial and final waveform data serve as a validation of the recorded potentials.

Data Processing. After completing the field survey, the data are downloaded from the data logger or transferred from the written form to a computer with graphing software capabilities. The results of typical close-interval surveys are shown in Fig. 2 and 3.

Ohmic voltage drop (*IR* drop) correction of CIS may be achieved using a number of different methods. The most common method is the instant-off-potential method using synchronized-current interrupters installed at CP current sources. It is beneficial to measure both the uncorrected potential (the on potential) and the *IR* drop corrected potential in order to determine the level of *IR* drop correction. The magnitude of *IR* drop in CIS of pipelines with the current applied can aid in detecting locations of protective coating faults. Correction methods that apply *IR* drop to every reading provide the most accurate CIS potential data. Other methods include: CP coupons, stepwise current reduction, and waveform analysis.

IR drop may not be a significant concern when electrolyte, current densities, depth of burial, and coating condition are consistent, and the magnitude of the *IR* drop is known or considered to be negligible. *IR* drop correction information can also be applied to other surveys, such as future test point surveys.

External influences that can be current sources include:

- Foreign pipelines or other cathodically protected facilities that are electrically bonded to the pipeline being surveyed. These must be interrupted to measure potentials to the desired accuracy.
- Direct current transit and mine railway systems, and high-voltage dc power transmission can cause stray or induced currents through the electrolyte near the pipeline being surveyed. Additionally, long-line currents and telluric currents can cause currents along the pipeline. These currents cannot be interrupted, but can be measured by methods listed in the section "Dynamic Stray Current" in this article.

Current Interruption Cycle Time. Fast-cycle interruption is a term that usually refers

to an interruption cycle in which the off cycle is less than 1 s. The advantage of fast-cycle interruption is that an instant-off reading can be obtained at each reading location without slowing data collection, providing more information. A disadvantage of fast-cycle interruption is that this procedure requires a fast voltmeter, precisely synchronized interruption, and data acquisition software that can correctly differentiate between the on and instant-off potentials and transitions and can record accurate potentials. Because of the difficulty in synchronizing interrupters operating on a very short cycle, slow-cycle current interruption has been historically more common. Advances in electronics and GPS time controlled equipment have made extremely accurate timekeeping more practical.

It is often not practical to use slower cycles to obtain an instant-off potential at each reading location because of the time required to obtain both an on and an instant-off-potential measurement. A disadvantage of the slow-cycle interruption is that depolarization may occur during the interruption of the CP. Slow-cycle current interruption may or may not differentiate between on and instant-off potentials during data collection. When the data are differentiated, separate and continuous plots of on and instant-off potentials are usually provided. Slow-cycle surveys that do not differentiate the potentials during the survey may differentiate the on and instant-off potentials by visual interpretation of a graph of the potentials (saw-tooth graph, Fig. 3).

There are various methods to confirm the operation of the current interrupters. Oscilloscopic waveforms may be used to show that the interrupters that influence a location are synchronized (Fig. 4). Waveforms do not indicate influencing current that is not interrupted. Lateral potentials and measurement of metallic *IR* drop may be used to obtain an indication of influencing CP current that is not being interrupted or foreign currents that are causing *IR* drops in the off cycle.

Metallic *IR* drop is the component of potential drop that occurs in the metallic path of the measurement circuit, primarily in the pipeline, under normal conditions. The magnitude of metallic *IR* drop represents the net current in the pipeline between the two test points that may be different from the current at specific points within the segment. Metallic *IR* drop should be measured when possible and recorded at the end of each survey run. Metal *IR* drop can be measured by direct metal-to-metal potential measurement or by taking the difference between the near-ground (NG) and far-ground (FG) potentials. Metallic *IR* drop should be measured and recorded when applicable for both the on and off cycles. Electrical connections should be made at every available contact point in order to minimize voltage drops in the metallic path. Metallic *IR* drop for depolarized or native-state surveys should be measured to determine whether all influencing CP has been deactivated.

Fig. 4 Typical oscilloscopic wave form of fast-cycle interruption

Near-ground potentials should be measured and recorded at the start of every survey run, and NG and FG potentials should be measured and recorded at every contact point during the survey run and at the end of the survey run. The amount of current can be calculated when the resistance of the pipeline section is known. If the IR drop correction is effective, then theoretically there are no metallic IR drops in the off cycle (in the absence of long-line currents and of stray dynamic and static currents).

Lateral potentials or side-drain potentials should be measured and recorded at the start of each survey run. Lateral potentials are “on” and instant-off (when applicable) pipe-to-electrolyte potentials taken to either side of the pipeline. Side-drain potentials are the potential difference between two reference electrodes in the “on” and “off” cycles (when applicable): one located over the pipeline and the other at a distance to each side of the pipeline. Lateral potentials or side-drain potentials also may be measured and recorded at areas indicating possible problems. If the lateral or side-drain potentials indicate significant current to the pipe in the “off” cycle, an attempt should be made, when practical, to locate, determine the source of, and interrupt the influencing current. If significant errors are observed, the survey may be discontinued until the source of the error can be determined, and previously collected data should be evaluated for acceptable IR drop error. Errors that cannot be corrected should be noted in the CIS data. Lateral potentials or side-drain potentials for depolarized or native-state surveys should be measured to determine whether all influencing CP has been deactivated.

Dynamic Stray Current

Stray current is current through paths other than the intended circuit. Dynamic stray current refers to any stray current that is changing over time. Dynamic stray currents can come from many sources, including electric transit systems and telluric currents.

Recording the structure-to-electrolyte potentials over a time period, typically 24 h, can identify dynamic stray current. If deviations in the structure-to-electrolyte potentials are significant, stray-current correction of the survey results is warranted. Long-term data recordings of the structure-to-electrolyte potential at numerous locations are required to ascertain the influence of telluric currents on structure-to-electrolyte potential measurements. Telluric current effects on the structure-to-electrolyte potential are most significant at changes in direction of the pipeline or at electrical discontinuities, such as dielectric isolation devices.

One method of dynamic stray-current compensation is to correct the CIS potentials with the variation caused by dynamic stray current as recorded by stationary data logger(s). For the compensation to be effective, the structure-to-electrolyte potentials recorded in the CIS must be precisely synchronized with the stationary chart recorders, such as by use of the same time standard (such as universal coordinated time as provided by GPS).

The number and location of the static recorders required to effectively compensate for stray-current effects on the section of pipeline to be surveyed will vary. In areas of telluric current activity, stationary data loggers are typically connected to the pipeline at intervals not exceeding 5 km (3 mi). In areas of dynamic stray currents from dc traction systems, data loggers are typically connected to the pipeline at intervals not exceeding 2 km (1.25 mi).

Offshore Procedures

Close-interval survey can be performed on submerged pipelines, in marshy areas, and offshore using special equipment. Typically, the pipe location techniques and half-cell positioning are not as accurate as those for buried pipelines without considerable expense. Using visual or dead reckoning and dragging a reference electrode is the most inexpensive method of pipe location and electrode placement. Other methods include the use of divers, remotely operated vehicles (ROV), magnetometers, or electronic positioning that tracks the as-built coordinates of the pipelines. In marsh areas, other vehicles such as air boats and swamp buggies can be used.

Data Validation

The validation of CIS data requires the review and analysis of data gathered before, during, and after the survey. Because the main purpose of performing a CIS is usually to establish the CP level of an underground metallic structure and compare it with criteria established by industry standards, the accuracy of the pipe-to-soil

potentials is extremely important. Before the results can be properly interpreted, the data obtained during the survey must be validated. Many factors can cause invalid CIS data, including:

- Missing data
- Improper stationing or distance measurement
- Excessive scatter or high contact resistance
- Inaccurate reference electrodes or voltmeter
- Broken wires/high-resistance connections
- Improper IR drop/interruption
- High induced ac
- Improper line location

Missing data may result in a misinterpretation of survey results. Typical information required in survey records includes:

- Company and location name
- Line identification and size
- Starting milepost/station number
- Location and operating condition of dc sources influencing the survey area
- Technician identification
- Equipment identification, e.g., voltmeter, data logger, and reference electrode serial number and description (for traceability to calibration records)
- Type of connections
- ac pipe-to-soil potential
- Near-ground pipe-to-soil potential (on and instant-off, if an interrupted survey)
- Left and right lateral pipe-to-soil potentials (on-off)
- Type of reference electrode used
- Survey direction
- Survey increment
- Waveform (if a fast-cycle interrupted run)
- Date and time of survey
- Description of survey conditions
- Ending milepost or station number
- Reason for ending run
- Far-ground potential reading with current applied
- Far-ground potential reading with current interrupted (if an interrupted survey)
- Near-ground reading with current applied, if ending at a connection to the structure
- Near-ground reading with current interrupted (if an interrupted survey), if ending at a connection to the structure
- Calculated or measured metal IR with current applied, if ending at a connection to the structure
- Calculated or measured metal IR with current interrupted (if an interrupted survey), if ending at a connection to the structure
- On and instant-off (if an interrupted survey) near-ground casing-to-soil potentials at casing vents
- On and instant-off (if an interrupted survey) near-ground potentials at each metallic foreign line crossing
- Bond current and polarity at each bond location
- Potentials on each side of insulating flanges
- Structure or pipe depth of burial

- Existence of buried foreign metallic structures in the vicinity of the surveyed line

It is also important to include the aboveground features encountered along the pipeline right of way during the survey, such as pipeline appurtenances, line markers, and physical features such as hills, creeks, ditches, fences, and street and highway names; the stationing at starting and ending connection points and at key physical features should be compared to the engineering stations when provided. Key physical features should be entered as comments into the data stream and engineering station may be reset to match stationing.

Regardless of the type of CIS, when the integrity of a structure is surveyed, the length of time at which the CP system has been operating at the conditions in which the CIS was performed is very important and should be included on the pipe-to-soil potential profiles.

As can be seen from the above considerations, a detailed execution plan must be developed well before an operator starts collecting the pipe-to-soil potentials.

Data Interpretation

After performing a CIS, the results of the validation will indicate if the survey data were acquired properly, if additional considerations may be required, or if some sections may require reinspection. It is not uncommon to resurvey portions due to errors such as scatter, problems with *IR* drop correction (such as an uninterrupted dc source) or dynamic stray current. Close-interval validated data may be compared with industry standards to determine if adequate CP levels exist.

ACKNOWLEDGMENT

This article is based on a draft standard developed by NACE International task group TG 279.

Corrosion of Storage Tanks

Ernest W. Klechka, Jr., CC Technologies Inc.

STEEL STORAGE TANKS are the primary means for storing large volumes of liquids and gaseous products. The stored fluid could be water, but it could be a volatile, corrosive, and flammable fluid requiring special precautions for storage as well. It is extremely important to maintain the integrity of on-grade and buried carbon steel storage tanks for economic and environmental reasons (Ref 1–3). For water storage tanks, internal corrosion can result in changes in color (turbidity) and taste that would be of importance for potable water. For boiler feed water storage tanks, corrosion products in the water can result in damage to the boiler. There may be specific requirements for the stored products including temperature, pressure, and control of contamination. Metal loss from internal and external corrosion can reduce the service life of the tank. External corrosion can occur because of contact with the soil and moisture in the soil. The main causes of internal corrosion are contact with corrosive storage products and water collected on the bottom of the tank (introduced with the other product or condensed from the air). Interior surface of some storage tanks are coated or lined to prevent contamination of the stored product and to extend the useful life of the storage tank. Typically, potable water storage tanks are internally coated to prevent contamination of the water. Crude oil storage tanks and fuel storage tanks are typically coated over the entire floor and a meter up the wall. Some chemicals cannot be suitably stored in carbon steel tanks. See articles dealing with specific chemicals in this Volume for selection of materials of construction.

An important consideration is the impact of storage tanks on the environment. Regulations have been formulated to address the possibility of leaks and spills, emissions for the tanks, seepage from tanks into the ground, and safety. These regulations define stringent standards that manufacturers and users must follow.

Another consideration is the fact that by-products of internal corrosion can lead to reduced quality for the product stored in the tank. For example, the presence of iron oxides and water can be damaging to fuels, causing plugged filters and freezing in cold environments.

Storage tanks can be broadly divided on the basis of their installation into aboveground

storage tanks (ASTs) and underground storage tanks (USTs). Aboveground tanks are common means for storing liquid hydrocarbon products such as crude oil, aviation fuels, diesel fuel, gasoline, and other refined products. Underground tanks are often used for dispensing and storage of home heating oil, gasoline, and diesel fuel.

Soil-side external corrosion of both ASTs and USTs can be mitigated by the use of cathodic protection (CP) with or without the use of protective coatings. Proper design, installation, and maintenance of CP systems maintain the integrity and increase the useful life of ASTs and USTs. High-quality dielectric protective coatings compatible with CP can be applied to properly prepared surfaces on the exterior of USTs and to the exterior tank bottom of ASTs (Ref 4). Aboveground steel tanks are typically designed for 20 to 30 years of useful life. Without CP or coatings, tank bottoms may have to be replaced after a few years (Ref 5).

Soil Corrosivity

Corrosion is generally worst where the tank is in contact with the soil. Resistivity of the backfill or sand under the AST or bedding and padding surrounding the UST is an important factor in determining how aggressive that environment is. Table 1 shows the relative degree of corrosion that can be expected based on soil resistivity.

Soil Characteristics. The pH and the presence of chloride and sulfate ions in the soil can have a significant effect on the corrosion rate of metals in soils. Chloride and sulfate contamination can be naturally occurring or the result of site contamination. Sulfate ions can be a source

of food for microbes and can result in micro-biologically influenced corrosion (MIC). Above 10,000 ppm, sulfate ions in the soil can have a severe effect on the degree of corrosion.

Chlorine ions are depassivating agents and cause pitting corrosion. ASTM D 512 (Ref 7) is a method to measure chloride ion concentration. As shown in Table 2, concentrations less than 500 ppm of chloride ions usually do not contribute significantly to corrosion; those above 5000 ppm can contribute to severe corrosion.

Sulfide ion in the soil can indicate the presence of anaerobic bacteria which can greatly accelerate the rate of corrosion. Corrosion rates in excess of 4 mm/yr (0.16 in./yr) have been measured in the presence of anaerobic bacteria. The test procedure shall satisfy the requirements of American Public Health Standard Method 4500, which is equivalent to U.S. EPA 376.2.

Acidity. As the soil pH decreases below 5.5 (acidic), the corrosion rate of steel increases very rapidly and can easily exceed 2 mm/yr (0.08 in./yr). When the soil pH is greater than 7.5 (alkaline), corrosion of carbon steel will be mitigated to very low levels. Cathodic protection will normally increase the pH near the cathode and conversely decrease the pH near the anode. Table 2 gives the general degree of corrosivity for chlorides, sulfates, and pH conditions.

Table 2 Effects of chlorides, sulfates, and pH on corrosion of buried steel

Concentration, ppm	Degree of corrosivity
Chloride ions	
>5000	Severe
1500–5000	Very corrosive
500–1500	Moderate
<500	Threshold
Sulfate ions	
>10,000	Severe
1500–10,000	Very corrosive
150–1500	Moderate
150	Negligible
pH	
<5.5 (acidic)	Severe
5.5–6.5	Moderate
6.5–7.5	Neutral
>7.5 (alkaline)	None

Source: Ref 6

Table 1 Approximate indication of soil resistivity versus degree of corrosivity

Soil resistivity, $\Omega \cdot \text{cm}$	Corrosivity
0–500	Very corrosive
500–1000	Corrosive
1000–2000	Moderately corrosive
2000–10,000	Mildly corrosive
>10,000	Negligible (very low levels of corrosion)

Cathodic Protection

Cathodic protection is a proven method of controlling corrosion of buried or submerged metallic structures. Design, installation, and maintenance of CP for the exterior bottoms of carbon steel ASTs and the external surfaces of USTs can mitigate corrosion.

Cathodic protection can be applied to new or existing tanks, but cannot protect carbon steel surfaces that are not in contact with an electrolyte. During testing, the tank should be partially filled in order to ensure contact with the soil.

If coatings are used in conjunction with CP the coatings must be compatible with the CP, resist cathodic disbondment, resist abrasion, and be flexible enough to withstand filling and emptying of the storage tank. External tank bottom coatings for ASTs can be damaged during welding and weld repairs. Aboveground storage tanks with external tank bottom coatings should be repaired using nonweld repair techniques.

Galvanic (sacrificial) and impressed current methods, like a corrosion cell itself, requires four components: anode, cathode, an electric path, and an electrolyte. Galvanic CP uses an active metal (anode), such as zinc or magnesium, in electrical contact with a more noble metal (cathode), such as a carbon steel structure, in an electrolyte such as soil. The active metal corrodes, generating an electric current that protects the more noble metal. Impressed current cathodic protection (ICCP) uses an external power source to provide the direct current (dc) that flows from the anode and the cathode through the electrolyte (soil) and returns through an external circuit. System characteristics are compared in Table 3.

Cathodic protection systems should be operated continuously to maintain polarization. Access for testing and monitoring of the CP system must be considered during design, and these activities should be part of the operating procedures for the AST or UST.

The size, type, and location of anodes and reference electrodes are determined during design. Potential interference with external liners (for product release control) and buried piping should be considered. Electrical interference with other CP systems should be resolved. Grounding system for storage tanks can result in mixed potentials because of the copper used for grounding and can affect the initial potential of the carbon steel AST or UST. As a result of mixed potentials, the amount of

current needed for CP may be increased to protect the grounding system (Ref 8).

Cathodic protection criteria are based on consensus industry standards. NACE International RP0169 (Ref 9) addresses underground or submerged metallic piping systems, RP0193 (Ref 2) addresses external corrosion of ASTs, while RP0285 (Ref 3) considers USTs. Corrosion control can be achieved at various levels of cathodic polarization depending on the environmental conditions. Based on RP0169, RP0285, and RP0193—all of which have the same criteria for CP—piping, AST tank bottoms, and USTs meet the criteria when the structure-to-soil potential meets one of these three criteria:

- A negative (cathodic) potential of at least 850 mV with the CP current applied. This potential shall be measured with respect to a saturated copper/copper sulfate reference electrode (CSE) contacting the electrolyte. Consideration must be given to voltage drops other than those across the structure-to-electrolyte boundary for valid interpretation of this voltage measurement. Consideration is understood to mean the application of sound engineering practice in determining the significance of voltage drops by methods such as measuring or calculating the voltage drop, reviewing the historical performance of the CP system, evaluating the physical and electrical characteristics of the tank bottom and its environment, and determining whether or not there is physical evidence of corrosion.
- A negative (cathodic) *IR*-free polarized potential of at least 850 mV relative to a CSE.
- A minimum of 100 mV of cathodic polarization between the carbon steel surface of the tank bottom and a stable reference electrode contacting the electrolyte. The formation or decay of polarization may be measured to satisfy this criterion. Although the 100 mV criterion can be a valuable approach to confirming CP, it is not popular in the CP industry. This is possibly because the test for the 100 mV polarization shift is more costly, requiring extra time for the development or decay of cathodic polarization than the tests for other criteria, or possibly because applications of the 100 mV polarization shift are not widely understood. See Ref 10 to 12 for more on the 100 mV criteria. See the article “Cathodic Protection” in Volume 13A for CP criteria in general.

The 100 mV polarization shift criterion may not be valid, especially where dissimilar metal couples such as copper ground grids and steel tanks are involved. The 100 mV polarization shift criterion also may be inappropriate for sulfate-reducing bacteria (SRB) containing soils, interference current, or telluric currents. More CP current may be needed to overcome the reduced pH caused by bacterial activity. Interference and telluric currents make interpretation of structure-to-soil potential difficult.

Some ASTs are built with a double steel bottom and the space between the two bottoms is filled with high-resistivity dry sand. In this environment, achieving a -850 mV CSE polarized potential is usually not practical. For ASTs with double bottoms, the 100 mV criteria is recommended.

For effective CP, the tank bottom of an AST must be in contact with the electrolyte (soil). During testing to the CP criteria, the tank should be partly filled (approximately $\frac{1}{3}$ full) to ensure adequate contact between the tank bottom and the soil. Some additional time may be needed for testing to allow for polarization of the tank bottom. Underground storage tanks are usually in good electrical contact with the soil, provided the soil has been properly compacted.

Alternative Reference Electrodes. Occasionally, reference electrodes other than CSE are used to measure the structure-to-soil potential of a tank. These electrodes include standard calomel electrodes (SCEs), silver/silver chloride electrodes (Ag/AgCl), and zinc electrodes. Copper/copper sulfate reference electrodes are used for measuring potentials in soils. Standard calomel electrodes contain mercury and are often used in the laboratory, but seldom in the field. Chloride contamination of a CSE will result in an error in the measurement. Therefore, silver/silver chloride electrodes (Ag/AgCl) are used in seawater and brackish water. Zinc electrodes are used for their long life and can be used inside tanks, under ASTs, and next to or under USTs. Inside-of-tanks zinc reference electrodes can be used as a stationary reference electrode to test the structure-to-electrolyte potentials. Zinc reference electrodes are often buried with stationary CSE or Ag/AgCl reference electrodes under tanks or next to USTs to verify the accuracy of the stationary reference electrode. Conversion values are given in Table 4.

Data Needed for Corrosion Protection Design

Prior to designing a CP system (alone or in conjunction with a protective coating system), information should be gathered and evaluated on:

- Construction data for the tank, piping, and grounding systems: site plans and layout, detailed construction drawings, date of

Table 3 Cathodic protection system characteristics

	Galvanic (sacrificial)	Impressed current
External power required	None	Required
Driving voltage	Fixed, limited	Adjustable
Available current	Limited, based on anode size	Adjustable
Satisfied current requirement	Small	High
Suitable environment	Lower resistivity environments	Higher resistivity environments
Stray-current consideration	Usually no interference	Must consider interference with other structures

Source: Ref 6

construction, material specifications and manufacturer, joint design and construction (e.g. welded, riveted), containment membranes (impervious linings), double-wall or secondary bottoms, coating specifications

- Other existing or proposed CP systems
- Availability of electrical power (for ICCP)
- Backfill information: soil resistivity and type of tank backfill material
- History of the tank foundation
- Unusual environmental conditions, including soil contamination and weather extremes, local atmospheric condition
- Operating and maintenance history of the tank including leak history (internal or external corrosion)
- Water table and site drainage
- Type and levels of liquid contained in the tank
- Nearby structures
- Operating temperature (See article "Corrosion under Insulation" in this Volume if relevant)
- Electrical grounding systems

Pre-design Site Assessment. For existing tanks, determine the extent of existing corrosion. Corrosion data and history may indicate that a new tank is needed or that major repairs are required (Ref 13, 14). Corrosion products "plugging" leaks may loosen and leak when a new CP system is applied. Field procedures for determining the extent of existing corrosion may include:

- Visual inspection
- Measurement of tank plate thickness (ultrasonic testing, coupon testing, physical measurement)
- Estimated general corrosion rates through electrochemical procedures
- Magnitude and direction of galvanic or stray current transferred to the tank through piping or other interconnections
- Soil characteristics: resistivity, pH, chloride ions concentration, sulfide ion concentration, moisture content
- Degree of corrosion deterioration based on comparison with data from similar facilities subject to similar conditions
- Data pertaining to existing corrosion conditions should be obtained in sufficient quality to permit reasonable engineering judgments. Statistical procedures should be used in the analysis, if appropriate.

Electrical isolation of structures must be compatible with electrical grounding requirements of applicable codes and safety requirements. If the tank bottom is to be cathodically protected, the use of alternatives to copper for electrical grounding materials, such as galvanized steel and galvanic anodes, should be considered. Electrical isolation of the tank from piping and other interconnecting structures may be necessary for effective CP or safety considerations.

Tank Electrical Characteristics. When examining an existing tank, several measurements should be made to determine the electrical characteristics of the tank:

- Tank-to-earth resistance tests
- Tank-to-grounding system resistance and potential tests

Soil-Resistivity Measurement. Soil resistivity is important to the design of either CP system. Soil-resistivity values measured at multiple locations are needed to determine the type of CP (galvanic or impressed current) required and the configuration for the anode system. Resistivity can be determined using the four-pin method described in ASTM G 57 (Ref 15) with pin spacing (a) corresponding to the depth of interest for burying the anodes (Fig. 1). As a general guideline, resistivity data should be obtained at a minimum of two locations per tank. For sand used as bedding around USTs and under ASTs, resistivity can be measured using a soil box and the same meter as in the four-pin method.

Soil resistivity is calculated using the resistance measured on the four-pin resistance meter and:

$$\rho = 2\pi aR$$

where ρ is soil resistivity ($\Omega \cdot \text{cm}$), a is the distance (in cm) between probes (and depth of interest), and R is the soil resistance (Ω) measured by the instrument.

If deep anode groundbeds are considered (Fig. 2), soil resistivity should be analyzed using

procedures described by Barnes to determine conditions on a layer-by-layer basis (Ref 6). For a Barnes layer analysis, several measurements are made at increasing pin spacing centered on a fixed point between the two center pins. The average resistivity and the resistivity for each layer can be calculated.

On-site resistivity data can be supplemented with geological information from other sources including water-well drillers, oil and gas production companies, the U.S. Geological Survey Office, and other regulatory agencies.

Testing for Current. Cathodic protection current requirements can be established using test anode arrays simulating the type of groundbed planned. Test currents are applied using suitable dc sources. Test groundbeds can include driven rods, anode systems for adjacent CP systems, or other temporary structures that are electrically separated from the tank being tested. Small-diameter anode test wells may be appropriate and should be considered if extensive use of deep anode groundbeds are being considered.

The applied current is measured. On the tank, the initial potential and the potential shift is measured. Based on these measurements,

Fig. 1 Soil-resistivity testing by the four-electrode test method. Current is applied to the outside electrodes (pins C1 and C2), while potential is measured on the inside pins P1 and P2. The pins are placed in a line and equally spaced (a) to simplify resistivity calculation (in text). This resistivity is the average resistivity of a hemisphere of radius (a). Source: Ref 15

Fig. 2 Typical deep anode groundbed CP system. Groundbed can be 20 m (65 ft) to several hundred meters deep. Source: Ref 2

Table 4 Conversion of voltage measurements at 25 °C (77 °F)

Reference electrode used to measure potential	Electrode potential(a), V vs SHE	Measured potential, equivalent to -0.85 V vs CSE	Value added to measured potential to correct it to a potential vs CSE
Copper/copper sulfate (CSE)	+0.300	-0.850 V	0.000 V
Saturated calomel (SCE)	+0.241	-0.791 V	-0.059 V
Silver/silver chloride (Ag/AgCl) in seawater	+0.250	-0.800 V	-0.050 V
Zinc (Zn) in seawater	-0.800	+0.250 V	-1.100 V

(a) Standard hydrogen electrode (SHE), also called normal hydrogen electrode (NHE). See the article "Reference Electrodes" in Volume 13B for temperature coefficients.

the current needed to protect the tank can be calculated.

If test data are not available, the current required for an UST or AST can be calculated. Typically, for tanks with sand backfill the bare surface area of the tank can be protected using 10 to 20 mA/m² of CP current. See the article "Cathodic Protection" in Volume 13A for details on calculations.

Stray Currents. Underground structures are subject to dynamic and static stray currents. Dynamic stray currents vary in magnitude and often in direction and can be caused by welding shops, electrically powered rail transit, and improperly grounded or faulted electrical equipment. Dynamic stray currents can be man-made or natural in origin. Static stray currents can be caused by other CP systems. See the article "Stray Currents in Underground Corrosion" in this Volume. Stray currents caused by a pipeline CP system in close proximity to a tank farm are shown in Fig. 3. The location where the stray current leaves the tank and returns to the pipeline is where stray current corrosion will occur.

Stray currents can be reduced by bonding to the foreign CP systems, adding galvanic anode discharge points, adding or changing the location of current drains, moving anode groundbeds, or as a last resort by the addition of more CP. Bonding to the foreign structure allows the current to return to the foreign structure through the bond and not by discharging from the tank. Adding galvanic anodes at the discharge point gives the current a low resistance path for the stray current to discharge; the anode corrodes because of the discharge. Changing the current drain locations and changing groundbed locations can improve current distribution and reduce stray currents. Adding more CP can overcome the effects of stray currents, but may result in increased stray currents in other locations.

The presence of stray currents may result in CP current requirements that are greater than those required under natural conditions. Dynamic stray currents can be detected by monitoring fluctuations in the CP potential over a period of time, usually 24 h. Static stray currents caused by other CP systems can normally be detected by interrupting individual CP systems

and monitoring the tank for CP potential fluctuations.

New CP designs should minimize electrical interference on structures not included in the protection system and any existing CP systems. Predesign test results can be analyzed to determine the possible need for stray current control provisions.

Intended Use of Storage Tank. Obviously, the materials stored in existing tanks and the intended use of new tanks will determine the design of internal corrosion-control measures. The coatings, lining, and inhibitors used to control corrosion of the internal surfaces of both ASTs and USTs must be compatible with the products to be stored. Frequently, CP is also applied inside surfaces of storage tanks.

The interior of water storage tanks, with their large surface areas, are frequently protected with compatible coatings and ICCP. Consumption of sacrificial anodes could result in contamination of the water. The use of inhibitors with water systems is discussed in "Corrosion Inhibitors in the Water Treatment Industry" in Volume 13A.

Crude oil storage tanks are frequently internally coated with two-part epoxy coatings over the entire floor and for the first meter (yard) up the wall to prevent corrosion because of water accumulation. Water accumulates as a result of condensation of the water vapor in the air pulled into the tank when the tank is emptied. Supplemental galvanic CP is frequently used in crude tanks.

The use of inhibitors in petroleum facilities is discussed in the articles "Corrosion Inhibitors for Oil and Gas Production" and "Corrosion Inhibitors for Crude Oil Refineries" in Volume 13A.

Soil-Side Corrosion Control

Generally a combination of CP and protective coatings is used. Sacrificial CP anodes are consumed as they generate electric current. The consumption is calculated as:

$$W = E \cdot CR \cdot I \cdot L$$

where W is the weight (mass) loss, E is efficiency, CR is the consumption rate (kg/A·yr), I is total current (A), and L is life or time (yr). Current efficiency for magnesium anodes is typically 50%, for aluminum anodes approximately 95%, and for zinc anodes between 90 and 95%. The CR for magnesium is 7.9 kg/A·yr, for aluminum 3.1 kg/A·yr, and for zinc 11.8 kg/A·yr.

Depending on the CP design, for crude tanks sacrificial anodes may need to be replaced as frequently as every 10 years, but they would be the choice where power is unavailable.

Impressed current cathodic protection is supplied with electric power, usually through a transformer and rectifier. The amount of current can be adjusted to account for changes in the

coating condition and the surface area to be protected. As the external coatings deteriorate with time, the amount of current supplied can be increased.

All USTs are good candidates for CP systems. Many USTs are fabricated and coated with pre-designed sacrificial CP systems. For ASTs and USTs, if necessary, CP can be applied inside secondary containment.

Protective coatings are often the first line of defense against corrosion. For carbon steel USTs, a coal tar epoxy or other barrier-type coating material is often used to isolate the metal from the electrolyte.

The exterior surfaces of an AST tank bottom is normally not coated, leaving large surface areas to be protected by CP. Plates are normally arranged on the tank foundation and welded in place. As a result, relatively large CP current is needed and ICCP is typically used.

However, when the tank bottom exterior is coated it typically is coated with a coal tar epoxy or a two-component epoxy coating material. The external surface of AST bottoms can be coated by applying external coating to the bottom place before welding, leaving the weld lanes bare. Up to 80% of the external tank bottom can be coated this way. Alternatively, the AST external bottom can be coated by lifting the tank and abrasive blasting and coating the bottom. Aboveground tanks with external bottom coatings should be repaired using nonwelding techniques such as glass reinforced overlays or adhesive bonding and coating of repair patches.

NACE Standard RP0169 (Ref 9) gives requirements and desired characteristics for coating in conjunction with CP:

- Effective electrical isolator. Because soil-side corrosion is an electrochemical process, reducing current flow by isolating the steel from the environment electrolyte reduces the uniform corrosion rate. The coating system should maintain constant electrical resistance over long periods of time to minimize changes in the CP current required.
- Effective moisture barrier. Water transfer through the coating can cause blistering and will contribute to coating failure and corrosion.
- Easily applied with a minimum of defects (holidays). Multiple coatings decrease number of through defects.
- Resists the development of holidays over time. After the coating is buried, minimal coating degradation and minimal damage from soil stresses and soil contamination occur.
- Good adhesion is needed to prevent water ingress and migration under the coating (undercutting).
- Toughness—the ability to withstand handling, storage, and installation with minimal damage—is required.
- The ability to withstand cathodic disbondment is required.
- The coating should be easy to repair.

Fig. 3 Stray-current corrosion caused by electrically common tanks picking up current from pipeline protection anode bed. Corrosion is most severe where current density leaving tank is highest (arrows). Source: Ref 2

- The coating should be environmentally friendly, nontoxic, inert, and easily disposed of.

Coatings are important factors in CP engineering. If the structure is coated, it is necessary to protect only the exposed metal at holidays, greatly reducing the size and cost of the CP system.

Aboveground Storage Tanks

The effectiveness of the coatings and CP systems, internal and external, affect the life of the AST. When calculating the remaining life of an AST, the internal and external corrosion rates are considered (Ref 16).

External Aboveground Coatings for ASTs. External coatings must be able to withstand atmospheric corrosion, the temperature of the stored material, and flexing of the tank. External surfaces of ASTs are frequently primed with inorganic zinc, organic zinc, or a high-performance primer coating. Epoxy and polyurethane protective top coats are often used to provide atmospheric corrosion control for ASTs.

Frequently, aboveground storage tanks are painted white to reflect solar radiation. By minimizing solar heat gain, the amount of vapors released from a tank containing volatile hydrocarbon can be reduced.

Foundations. Aboveground storage tanks on ring-wall foundations with plastic liners to detect and contain leaks can be protected by anodes and reference electrodes installed in sand between the liner and the tank bottom (Ref 17). The following factors should be considered when evaluating the method of CP. Replacing galvanic anodes under the tank can be very expensive. The flexibility and adjustability of ICCP is desirable. Rectifiers for ICCP typically require bimonthly inspection.

For both systems, reference electrodes placed at the center and at several other locations beneath the tank bottom enable tank bottom potential monitoring. For small tanks, diameter less than 20 m (66 ft), tank-to-soil potentials can be measured at four locations around the tank periphery. For larger tanks, slotted casings can be installed underneath the tanks to measure the potential profile under the tank.

Foundation characteristics such as material of construction, thickness of ring walls, and water drainage are important in the assessment of the extent of existing corrosion.

For existing tanks, current requirement tests can be conducted to determine the amount of CP current needed to protect the tank. For new tank bottoms, an estimation of the amount of CP current needed to protect the tank can be calculated by using approximately 10 mA/m² for bare steel, or by measuring the current required on similar tanks in a similar environment. This initial value for polarizing the bare metal is considerably higher than the current density required to maintain protection.

Regulations. Containment of petrochemicals, petroleum products, hazardous chemicals, hazardous waste, and similar regulated substances in ASTs is a concern for soil, air, surface water and groundwater contamination. Loss of integrity to the tank and releases of the regulated substances may be due to corrosion, structural defect, inadequate maintenance and repair, or improper installation or operation. In order to minimize impact to the environment, secondary containment is required. Secondary containment must be impermeable and can be concrete for smaller tanks or containment liners for larger tanks.

Industry standards for the design, operation, and maintenance of ASTs are given in Table 5. It is always good practice to use the current standard. Some regulations are part of the Federal Code, such as liquid pipeline breakout tanks, which are covered by 49 CFR Part 195.

Potable water tanks should comply with ANSI/NSF 61. American Water Works Association standards for storage tanks include: D100, Welded Steel Tanks for Water storage; D102, Coating Steel Water-Storage Tanks; D104, Automatically Controlled Impressed Current Cathodic Protection for the Interior of Steel Water Tanks.

Anode Systems. The three most common galvanic anodes used to protect tank bottoms are standard magnesium anodes, high potential magnesium anodes, and high-purity zinc anodes. The selection and use of these anodes should be based on the current requirements, soil conditions, temperature, and cost of materials.

High-purity zinc anodes should meet the requirement of ASTM B 418 type II anodes (Ref 24). The purity of the zinc greatly affects the performance of the galvanic anode. Zinc anodes should not be used if the soil temperature around the anode might exceed 49 °C (120 °F). Higher temperatures can cause passivation of the zinc anode. The presence of salts such as carbonates, bicarbonates, or nitrates in the electrolyte may

also reduce the performance of zinc anode materials by causing passivation.

Galvanic anode performance may be enhanced in most soils by special backfill materials. Mixtures of gypsum, bentonite, and sodium sulfate are the most common packaged anode backfill materials.

Monitoring to verify CP must also verify that current is reaching the entire tank bottom. For tanks less than 20 m (66 ft) in diameter, measurements around the exterior of the tank may be sufficient to determine the level of the CP. For large-diameter tanks, permanent reference electrodes placed under the tank can help to determine the CP potential distribution on the exterior tank bottom. Slotted nonconductive tubes can also be placed under the tank to measure CP potential profiles under a tank.

Soil Contact. For the CP system to function properly, the tank bottom must be in contact with the soil. On large-diameter ASTs, the bottom acts as a diaphragm compressing the soil under the tank bottom. When the tank is emptied the bottom may bulge upward, losing contact with the soil. Once soil contact is lost, the CP system cannot protect the steel that is not in contact with the soil.

Vertically drilled anodes are distributed around the tank to give uniform current distribution (Fig. 4). The negative lead from the rectifier is connected to the tank. The positive lead from the rectifier is connected to the anodes through a junction box. The junction box allows for monitoring current measurement to the anodes. Reference electrodes should also be installed as part of the monitoring system. This system is effective for small-diameter tanks, less than 20 m (66 ft), as long as the anodes are installed above a secondary containment membrane.

Angle-drilled anodes are a variation of the vertically drilled anode system. In order to get more current under the tank, the anodes are placed under the tank in holes drilled at an angle

between 30° and 45° (Fig. 5). This system is effective on tanks typically less than 55 m (180 ft). Monitoring systems should also be installed when installing this type of system.

Deep-anode groundbeds are a common CP construction method used to distribute current over large areas uniformly. Deep-anode groundbeds can be drilled vertically from 20 to several 100 m deep. Typically graphite, cast iron, or mixed-metal-oxide anodes are used in

deep-anode groundbeds. The negative return to the rectifier is connected to the tank (Fig. 2).

Deep-anode systems provide the greatest current distribution and are used on large storage tanks up to 100 m (330 ft) where current can access the tank bottom. These systems do not work well with secondary containment barriers because the current frequently must pass through the barrier, which is a high resistance path to get to the tank bottom.

Fig. 4 Vertically drilled anode CP system, plan and elevation views. Source: Ref 2

Fig. 5 Plan and elevation view of angle drilled anode CP system. Source: Ref 2

Fig. 6 Horizontally drilled anode system. Source: Ref 2

Horizontally Installed Anode Groundbed. In order to distribute current under a tank, anodes can be horizontally installed under a tank. If the tank has a secondary containment lining, this method can be used. Anodes installed in a perforated nonconductive tube can be removed and replaced if necessary (Fig. 6).

These systems work well for all size tanks provided the anodes can be installed above any secondary containment barrier. If the system is installed outside of a secondary containment barrier, the current will have to pass through a high resistance path and will have a great deal of difficulty providing CP.

Double-Bottom Cathodic Protection Layout. Nonconductive containment liners also prevent the flow of CP current outside the barrier from reaching the external tank bottom.

Repairs to corroded tank bottoms can be accomplished by installing a double bottom. A nonconductive liner is placed over the existing tank bottom. An anode system is placed on top of the liner on the original tank bottom along with monitoring reference electrodes. High-resistivity sand is used to fill the space between the original floor and the new floor installed in the tank (Fig. 7).

In order to distribute the current evenly, the anodes are typically installed in a grid pattern as shown in Fig. 8. Either high-purity zinc or magnesium ribbons or rods are used as sacrificial anodes. For zinc anodes, the temperature of the space between the double tank bottoms should not exceed 49°C (120°F) to prevent passivation.

Impressed current anode design is more common for double-bottom applications. Typically metal-oxide-coated titanium ribbons or wires or other linear anodes are used for the anode material (Fig. 9). Leads from the rectifier are connected to each anode through a junction box where current to each anode can be measured.

Reference electrodes are installed in order to evaluate the distribution of current on the tank bottom (Fig. 9). They measure the polarized potential distribution under the tank.

Fig. 7 Typical double bottom tank impressed current (ICCP) anodes layout. Sacrificial anodes can be placed in a similar fashion. Tube is a perforated nonmetallic tube for monitoring CP system.

Fig. 8 Plan view of sacrificial anode grid pattern. Source: Ref 2

Fig. 10 Perforated nonmetallic pipe for monitoring the CP potentials under the tank bottom. Source: Ref 2

A perforated nonconductive tube can be directionally drilled and placed under the tank (Fig. 10). A permanent reference electrode can be installed in the tube, or a portable reference electrode can be used to measure the potential profile under the tank.

If necessary, water can be introduced into the perforated tube with the reference electrode in order to maintain good soil contact during testing.

Underground Storage Tanks

An underground storage tank is defined by the U.S. Environmental Protection Agency (EPA) as a tank and any underground piping connected to the tank that has at least 10% of its combined volume underground. Under the EPA UST program, a tank owner must notify a designated state or local agency of any tank storing petroleum or hazardous substances. Most regulated USTs store fuel for vehicles and are located at gas stations (Ref 23, 25).

Underground storage tanks have posed an environmental risk to groundwater because of the potential for leaks, overflow, or faulty equipment. In 1984, the EPA responded to the increasing risk by enacting a comprehensive regulatory program. These regulations, part of the Resource Conservation and Recovery Act, required owners or operators of underground storage tanks to be responsible for preventing, detecting, and cleaning up releases. The EPA has allowed states to implement and enforce UST regulations that either meet or exceed the EPA regulations. The industry standards listed in Table 5 for underground storage have served in

Fig. 9 Impressed current grid using wire anodes. Plan view. Source: Ref 2

Fig. 11 Impressed current anode system for a UST

part as the basis for the standards enacted by federal and state regulators.

Organic coatings may be applied to both the interior and exterior of underground steel tanks. Interior coatings prevent internal corrosion and extend the life of the tank. In the case of shop-assembled tanks, coating and linings are generally applied at the factory.

A high-quality dielectric coating should be applied to a properly prepared surface of the exterior areas of the UST including anode connections, attachments, and lifting lugs. Crevice or corner areas that restrict coating coverage should be seal welded prior to coating. Any type of coating used on a steel tank must have high dielectric properties. The dielectric coating isolates the tank electrically from the environment while reducing demands on the CP system. Other properties necessary in a dielectric coating are resistance to environmental fluids and the product being stored, impact/abrasion resistance, adhesion, and resistance to cathodic disbondment.

Cathodic protection systems for new UST systems may be: factory-fabricated galvanic, field-installed galvanic, or field-installed ICCP. The recommended practices with respect to field-installed systems are similar to those for existing UST systems; vertical sacrificial or impressed anodes can be installed. Consideration must be given to voltage drops other than those across the structure-to-electrolyte boundary, the presence of dissimilar metals, and the influence of other structures that may interfere with valid interpretation of structure-to-soil voltage measurements.

Typically, ICCP anodes are placed around the UST as shown in Fig. 11. Typically, factory-installed sacrificial anodes are located at each end of the tank. Additional field sacrificial anodes can be installed as shown in Fig. 11 to provide better current distribution. Galvanic anode can be installed in a similar manner.

Monitoring ASTs and USTs

Once an ICCP system is operational, the rectifier should be monitored bimonthly, measuring the rectifier output voltage and current and a structure-to-soil potential at a representative test point. The rectifier voltage and current are useful for tracking increases in circuit resistance and forecasting the anode service life. The structure-to-soil potential helps to identify changes in the level of CP caused by changes in soil resistivity, degraded coating, passivated anodes, or depletion of anodes. Unexplained changes in the structure-to-soil potential can be used as a trigger for additional CP surveys to identify the cause of the change in structure-to-soil potential and to develop remedial measures (Ref 4, 25).

Potential measurements should be made at least annually. These measurements should be made around the perimeter of the tank and at all permanent reference electrodes. If slotted casings are installed under the tank bottom of an AST, a potential profile should also be measured annually. These measurements should be made around the perimeter of the UST and all permanent reference electrodes.

Potential measurements should not be taken through concrete or asphalt. Typically, soil contact may be established through at-grade openings, by drilling a small hole in the concrete or asphalt, or by contacting a seam of soil between concrete and asphalt.

Well Casing External Corrosion and Cathodic Protection

W. Brian Holtsbaum, CC Technologies Canada Ltd.

THE PORTION OF THE WELL OF CONCERN is that portion of the casing in contact with the formation either directly or through a cement barrier. It must be noted that where multiple casing strings are used, only that portion of each casing string in contact with the formation applies to this discussion.

Well Casing Corrosion

The corrosion mechanism will vary depending on the depth and the conditions at various parts of the casing. Gordon et al. (Ref 1) reported corrosion on well casings above a depth of 60 m (200 ft) that was due to oxygen enhanced by chlorides and sulfates in the soil while below that depth corrosion was caused by carbon-dioxide-rich formation water. These conclusions were based on scale analyses, sidewall core analyses, and soil analyses. In addition to these mechanisms, galvanic corrosion (especially if the casing is connected to surface facilities), anaerobic bacteria supported by drilling mud, and stray-current electrolysis are other possible causes of corrosion (Ref 2). Cementing the casing in place helps reduce the corrosion rate but does not eliminate it (Ref 3).

The procedure for predicting the probability and/or rate of corrosion is given in NACE RP0186 (Ref 4) and can be summarized:

1. Study the corrosion history of the well or other wells in the area (Ref 5).
2. Study the downhole environment, including the resistivity logs, different strata, drilling mud, and cement zones.
3. Inspect any casing that has been pulled (Ref 1).
4. Review the results of pressure tests.
5. Review the results of downhole wall thickness tests (Ref 1).
6. Review the results of casing potential profiles (CPP).
7. Review the oil/gas/water well maintenance records.

In a given area, after the first leak has occurred, the subsequent accumulated number of

casing leaks often follows a straight-line relationship with time when presented on a semilog plot, that is, the log of the leaks versus time (Ref 5–7). This in effect means that the leak rate is increasing tenfold over equal periods of time. Repairs to the casing will alter this relationship as a repair often replaces several potential leaks; however, the leak rate will not be reduced to a tolerable level until cathodic protection is applied.

As part of many drilling programs it is common practice to pump cement into the annular space between the well borehole and the casing, usually to a point above the producing formation (sometimes from surface to producing formation depth and other times only portions of the casing strings are cemented) to achieve a seal. The cement in newer wells is often brought to the surface. However, in older wells, the cement was only sufficient to achieve a seal from the oil- and/or gas-bearing formation and therefore was brought from the bottom to a specific point along the casing. It should be noted that sections of casing pressed into the formation before cement injection will not necessarily have a cover of cement, or at the most, a very thin layer that is inadequate for corrosion control. Furthermore sections of casing not in the cement will continue to be exposed to the remains of the drilling mud.

The formation of corrosion cells can be:

- Local or pitting
- Between the cement and noncement sections of casing
- Between differential temperature zones
- Between brine formations and relatively inert rock
- Between the well casing and the surface facilities if there is a metallic connection

In addition, corrosive gases from a formation, such as carbon dioxide (CO_2) and hydrogen sulfide (H_2S) in an aqueous environment, can cause more aggressive attack.

Direct-current (dc) stray-current interference is another possible source of external corrosion. These may come from other cathodic protection systems, surface welding, or dc operated equipment. Alternating-current (ac) stray current in

high current densities can also be a source of corrosion (Ref 8). Stray current accelerates corrosion on the casing if it discharges into the formation when returning to its source.

Detection of Corrosion

The two principal methods for detecting well casing corrosion include metal-loss (corrosion-monitoring) tools and casing current measurement. Both are described in this section.

Metal-Loss Tools

Casing monitoring tools for corrosion consist of three basic types: mechanical tools, electromagnetic tools, and ultrasonic tools (Ref 9).

The **mechanical caliper tool** is the oldest method where many “fingers” are spaced around a tool mandrel. When the tool is pulled past an anomaly, these fingers either extend into a defect or are pushed in by scale, a dent, or a buckle in the casing.

Electromagnetic tools consist of:

- High-resolution magnetic flux leakage and eddy-current devices
- An “electromagnetic thickness, caliper, and properties measurement” device

The source of magnetic flux comes from the electromagnet (or permanent magnet) in the tool. As the tool moves along the casing, the magnetic flux through the casing wall is constant until it is distorted by a change in the pipe wall thickness. The flux leakage induces current in sensing coils that is related to the penetration of the defect in the casing wall. A uniform thinning of the casing wall may be detected only as a defect at the beginning and end as there may be little change in flux leakage in between. Strictly, a magnetic flux tool cannot discriminate between a defect in the inside or the outside of the casing.

However, by adding a high-frequency eddy current that can be generated in the same tool, which induces a circulating current through the inner skin of the casing wall, discrimination

between internal and external defects can be achieved. Sensing coils on the tool then detect the high-frequency field. A metal flaw or loss in the inside of the casing impedes the formation of circulating currents, and the change in this current is a measure of the surface quality and approximate vertical height of the defect. By comparing the defects from the electromagnetic to those obtained from the eddy-current signals in the tool, the external defects can be defined by a process of elimination.

The ultrasonic tool has transducers around the tool that act as both transmitters and receivers of an acoustic signal. The reflected signal is then analyzed for casing thickness, internal diameter, casing wall roughness, and defects. In addition, a cement evaluation can be included.

Tool Limitations. Since each tool has limitations, it may be necessary to run more than one tool depending on the type of flaw expected. In spite of the limitations, these tools can provide a reasonably accurate assessment of the casing metal loss; unfortunately, they can only detect corrosion damage after it has occurred.

Casing Current Measurement

According to Faraday's law (Eq 1), the metal loss due to corrosion is proportional to the dc current and the length of time that it leaves the metal and enters the electrolyte:

$$W = \frac{MIt}{nF} \quad (\text{Eq 1})$$

where W is weight loss in grams (g); M is the atomic weight in grams (g); t is the time in seconds (s); I is the current in amperes (A); n is the number of electrons transferred per atom of metal consumed in the corrosion reaction; and F is Faraday's constant (96,500 coulombs per gram equivalent weight).

For steel, this equates to a metal loss of 9.1 kg/A-yr (20.1 lb/A-yr). If the current can be measured then the metal loss, as a measure of weight, for a given period of time can be calculated.

An axial current at any point in the casing can be calculated from Ohm's law (Eq 2) by measuring a voltage (microvolt, μV) drop across a known length of casing resistance:

$$I_p = \frac{V_2}{R_p} \quad (\text{Eq 2})$$

where I_p is the axial current in casing (μA); V_2 is the axial voltage drop between two contact points along the casing pipe (μV); and R_p is the casing pipe wall resistance between the two contact points (Ω).

This voltage measurement is commonly called a casing potential profile (CPP), but the intent is to assess the axial and radial current profile in the casing. By determining an axial current value and direction between consecutive points in the casing, a radial current pickup or discharge can then be predicted in accordance with Kirchhoff's current law, which states "the sum of the current

at any junction must equal zero." Figure 1 illustrates three possible current measurement scenarios (A, B, and C); in all cases, the junction in Kirchhoff's current law is at the center of each scenario.

The anodic or corroding sections of a casing are at the sections of current discharge, while the current pickup areas are cathodic and are not corroding. Scenario A of Fig. 1 shows the axial current increasing from 1.5 to 2.0 A; therefore, there must have been a 0.5 A pickup in between, indicating that this section is cathodic. The current of 2.0 A coming up the casing in scenario B is greater than the 1.5 A that continues up the casing; thus, 0.5 A must have discharged from the section in between the two points, causing this to be anodic or corroding. The current of 1.0 A that is coming downhole at the top of scenario C is in the reverse direction from the 1.5 A coming uphole; therefore, the current coming into the casing section from both ends must discharge from the pipe section somewhere in between. This section is therefore anodic and would be corroding.

By measuring the axial current at regular intervals along the casing, a complete current map along the casing can be obtained as shown in Fig. 2. Such a test is called a casing potential profile (CPP), and the plot in Fig. 2 is called an axial current profile. Both the amount and the direction of current have to be determined to predict a current pickup or discharge. An increasing slope coming uphole (equal to a negative change in depth per change in current) indicates a current pickup (cathodic section), while the reverse slope indicates a current discharge (anodic section). The amount of metal loss can be predicted for a given period of time on the assumption that the relative current will remain the same.

Determination of the amount of current pickup and discharge along the casing in Fig. 2 results in the radial current profile shown in Fig. 3. Referring to Fig. 2, the direction of net current flow at about "85% of depth" is in the downhole direction as it crosses the zero (0) current axis, while the current below that depth is coming uphole. This causes a current discharge centering

Fig. 1 Example of radial current pickup or discharge from axial current. Refer to the text for a discussion of scenarios A, B, and C.

Fig. 2 Example of axial current profile in casing without cathodic protection

Fig. 3 Calculation of radial current profile from Fig. 2

at about 90% of depth as shown in Fig. 3. This is the same as scenario C in Fig. 1. In a similar fashion, the current at a depth between 0 and 25% and also 40 and 55% of depth is less than the current below, although in the same direction, which is the same as scenario B in Fig. 1. This also indicates a current discharge (anodic) area. The remainder of the casing in this example is picking up current and is cathodic, which fits the condition illustrated by scenario A in Fig. 1.

Limitations and Advantages of Casing Current Measurements. Casing current measurements, are only sensitive enough to measure long-line currents and do not detect local corrosion cells that exist between the spacing of the two contacts.

The advantage of this test is that macro-corrosion can be predicted before it occurs. However, the assumption that the current magnitude and location will stay the same can create a large error. The existence of local corrosion pits will be missed, and these can represent a large amount of the corrosion taking place (Ref 9, 10).

Cathodic Protection of Well Casings

At one time there was a concern that cathodic protection current applied at the surface would not reach the bottom of deeper well casings. Blount and Bolmer (Ref 11) conducted polarization tests with a reference electrode located at the top and the bottom of well casings and concluded that cathodic protection is feasible to a depth of at least 1000 m (3300 ft). Subsequent tests have shown that it is feasible to depths up to at least 3960 m (13,000 ft).

Two methods of determining the amount of cathodic protection current required are described in this section: a casing polarization ($E \log I$) test and a CPP test. The first test attempts to predict when the casing becomes a polarized electrode, while the second test confirms if an adequate amount of cathodic protection current is being discharged from the anode bed(s) to ensure current is being picked up along the length of the casing being tested.

$E \log I$ Test (Tafel Potential)

The $E \log I$ test is a measurement of the polarized casing-to-soil (electrolyte) potential (E) compared to the logarithm of different increments of applied current (I). The casing-to-soil potential is measured with respect to a remote reference electrode, often a copper/copper-sulfate reference electrode (CSE). "Remote" in this case is a point where the electrical voltage gradient is zero. Polarization is considered to take place at the intersection of the two straight lines as shown at point "A" in Fig. 4. At the intersection of the upper straight line (point "B"), the curve becomes a hydrogen overvoltage curve and obeys the Tafel equation.

In the early years, the point where the two straight lines intersected (Fig. 4, point A) was

taken as the current required for the protection of the well casing. This not only gave widely varying results depending on the relative slope of the two lines, but also provided current requirements that were found to be too low to protect the casings. The laboratory and field research of Blount and Bolmer (Ref 11) confirmed that the intersection of the upper portion of the Tafel slope with the curve was the point of corrosion control and proved to yield more consistent results (Fig. 4, point B). This point is normally used to establish a cathodic protection criterion for the casing.

A schematic of a typical $E \log I$ test is shown in Fig. 5. The test is conducted by impressing an increment of current for period of time and then measuring the "instant off" potential when the applied current is briefly interrupted. This process is repeated at increasing increments of current to a point beyond where the Tafel break in a plot between the instant off potential (E) and the logarithm of the current ($\log I$) occurs (point B in Fig. 4). There has been extensive experimentation both in the laboratory and the field (Ref 11–13) comparing the current increments

and the length of time at each increment to allow polarization to occur. The conclusion was that the best results occur when the increments of current and the time intervals between current increases are constant. A sufficient time interval must be established that ensures polarization will be complete before proceeding to the next current value. Although the current increment and time needs to be established for each $E \log I$ test, current increments of 0.5 A and time intervals of 10 min is often a practical combination. The time interval has been reduced to 5 min under certain circumstances where the well polarizes more quickly. It must be noted that too short of time intervals can yield an inaccurate higher current requirement as polarization may not be complete at given current values before the test current is increased incrementally.

Equipment (Fig. 6) can be set to automatically interrupt the current and record casing-to-electrolyte potentials continuously during the current interruption. In this way, the existence of a "spike" can be seen and the appropriate instant off casing-to-soil potential selected for each current interval. Furthermore, the current output

Fig. 4 An example of an $E \log I$ plot. Refer to text for a discussion of points A and B.

Fig. 5 Basic $E \log I$ test. CSE, copper/copper-sulfate reference electrode; dc, direct current.

can be controlled using silicon-controlled rectifiers (SCRs) to ensure that it remains constant during the test interval and that the desired fine incremental output control can be achieved.

Often a premature ending of the test occurs because the $E \log I$ profile was interpreted incorrectly as having straightened out. This variance is likely due to reactions that are taking place at different times or at different points as the test proceeds. To protect against stopping the test prematurely, a linear plot of E versus I should be made as the test proceeds to ensure that the test has left a straight-line relationship indicating that polarization is occurring. Often there is an early straight-line segment or the profile starts to leave the linear straight-line relationship only to return to the same slope. These early deviations are false indications as shown by the data from

Fig. 4 plotted on a linear profile in Fig. 7. The Tafel break of interest in the $E \log I$ plot is beyond that determined by the linear plot (12.5 A) and becomes the criterion for protection for that well casing, as shown by point B in Fig. 4.

Subsequent $E \log I$ analysis by this method has compared favorably to the current requirement determined by CPP test results provided that the break (Fig. 4, point B) was selected after the straight-line relationship has ended on a linear plot. When this method is not used, an erroneous analysis of the $E \log I$ test can be expected (Ref 14).

Advantages and Limitations. An advantage of the $E \log I$ test is that it can be performed while the well is still in production. However, the casing still should be electrically isolated from

all other structures for this test, or at least one must be able to measure the portion of the test current returning from the casing by perhaps using a clamp-on ammeter that can either fit around the wellhead or individually around all of the lines, instrument tubing, and conduit that connects to the well.

One disadvantage of the $E \log I$ test is the concern as to whether the test “sees” the lower part of the casing.

Casing Potential Profile

The CPP test for cathodic protection is similar to that described previously for predicting corrosion from casing current measurements except that now a current pickup is desired at all locations similar to that illustrated in Fig. 1 (scenario A). The casing has to be electrically isolated from all surface structures and the service rig during this test, otherwise the current returning at the wellhead must be measured.

The original CPP tool had two contacts that were 3 m (10 ft) to 7.6 m (25 ft) apart. The tool was stopped at regular intervals for microvolt (μV) measurements. Davies and Sasaki (Ref 13) describe a newer CPP tool (the CPET corrosion-protection evaluation tool) that has four rows of knife contacts that are 0.6 m (2 ft) apart between rows (Fig. 8). Measurements taken between the different rows of contacts include the pipe resistance, a voltage drop (μV_2) between the inner 0.6 m (2 ft) contacts, and another voltage drop (μV_6) across the outer contacts 1.8 m (6 ft) apart.

Pipe (Casing) Resistance Determination. Using a conventional four-pin resistance test (the same test is often used in conjunction with a resistivity measurement), the instrument

Fig. 7 Linear plot showing where the curve leaves a linear relationship. Tafel point on $E \log I$ must be at a higher current than the point that deviated from a linear straight line in this figure. Data generated from Fig. 4

Fig. 8 CPET casing potential profile tool. CPET, corrosion protection evaluation tool

impresses a known current (I_{test}) between the outer contacts and measures the resulting voltage (V_2) across the inner 0.6 m (2 ft) contacts. This then allows the casing resistance between these 0.6 m (2 ft) contacts (R_2) to be calculated by using Ohm's law ($R_2 = V_2/I_{\text{test}}$).

Casing Axial Current Determination. Once the pipe resistance for the test point has been determined the axial current can then be calculated by $I_2 = V_2/R_2$. Identical measurements and calculations are made across all other sets of contacts and the results averaged. Normally, the results across the 0.6 m (2 ft) and 1.8 m (6 ft) rows are reported ($I_2 = V_2/R_2$ and $I_6 = V_6/R_6$). The radial current is then calculated between consecutive current measurements noting current direction.

It must be understood that the current in the casing when measured at any given point is the accumulation of all of the current pickup less any discharge on the casing below that point. Also the cathodic protection current direction has to be toward the top of the casing in order to return to the dc power source. Therefore, only when cathodic protection has been successfully applied does a plot of the axial casing current continually increase from the bottom to the top of the casing, thus indicating a continuous current pickup.

Figure 9 illustrates two cathodic protection trials with current applied. From the plots it can be seen that trial 1 did not eliminate all of the anodic areas. Thus, the applied current was increased until the anodic areas were eliminated as indicated by the axial current increasing continuously from the casing bottom to top, trial 2.

Trial 1 in Fig. 9 shows an axial current pickup at all but two sections. One current discharge is at approximately 55% of depth and the other at approximately 85% of depth; both of which are identified by "downward" slopes on the profile. The axial current at 85% of depth is in the

Fig. 9 Sample casing potential profile axial current profile

downhole direction as it crosses the zero (0) current axis, while the current below is coming uphole. While the axial current at 55% of depth is in the same downward direction, the current above is less than that below, which also indicates a current discharge or an anodic section.

Since this was unsatisfactory, the current was increased for trial 2 (it must be noted that during an actual test, time must be given to ensure a steady state has been achieved after ampere adjustments before another log is run to obtain reliable results). Here, continuous axial current pickup occurred from bottom to top as shown by the positive slope in the accumulated current profile. The total current value established by this test now becomes the criterion for cathodic protection. It should be noted that errors can occur in this measurement due to poor contacts. However, this is the best technology available at the present time to determine the amount of cathodic protection current required to protect a well casing, or a portion of a well casing.

A partial CPET plot is shown in Fig. 10 that illustrates the axial current, radial current, and the casing thickness. The casing thickness is an estimate based on Faraday's law (Eq 1) and the assumption that the radial current discharge has remained the same over time. As a result, the casing thickness estimate may not be a true

Fig. 10 CPET axial and radial current plot with a conventional rectifier and casing thickness. Total current is 15.3 A.

measure of the wall thickness remaining. Experience has shown that there is often quite a discrepancy between corrosion-prediction losses by this method when compared to actual metal-loss measurements.

Factors Influencing the use of CPP Tests.

Even though CPP is probably the best means now available to establish the current required for a well casing, it is not often used. The main reasons are associated with the cost of running the tool, both direct and indirect costs. Some of the reasons include:

- In order to run the tool the well has to be taken out of service. This in itself limits the number of potential candidates unless there is a very urgent need to take a well out of service.
- Depending on the fluid in the well bores, many wells will have to be "killed" before the tool can be run.
- In order for the tool to make good contact with the casing, any scale or product buildup on the inside of the casing will have to be cleaned off before the tool is run.
- There are not many CPET tools available worldwide, and the older CPP tool is not available. Coordinating the work is therefore vital to ensure the well and the tool are available at the same time.
- A cathodic protection system: anodes, rectifier (or some other suitable dc power source), cabling, and so forth, must be constructed and operating in advance of the downhole log if the test is to verify a current requirement target.
- If the testing is to determine cathodic protection current requirements, then weeks or even months between runs might be necessary in order to allow a steady state to be achieved between output adjustments.
- Since completion practices for wells in the same producing area can vary significantly, multiple tests on multiple wells may be necessary to arrive at current return criteria that meet all of the well completion variations.

Mathematical Modeling of Total Current Requirement for Well Casing Cathodic Protection

Several mathematical models (Ref 15–19) have been developed to estimate the total current required to protect a well casing by cathodic protection that can be summarized:

- Current density
- An attenuation equation
- A modified attenuation equation
- A computerized equivalent circuit using formation resistivity, nonlinear polarization characteristics, and well casing information

The current density model applies an empirical current density to the surface area of other well casings of similar characteristics to the source of the empirical data to estimate the total current requirement of each well casing. The

variations in well depth and completion such as the amount of the casing that was cemented between it and the formation and the quality of the cement can make this approach quite inaccurate. Verification by field tests on typical well casings in a given geographical area is advised.

Attenuation calculations modified from those used on pipelines were applied initially to casings to estimate a potential at a given depth based on the potential change at the surface. The relationship developed by Schremp and Newton (Ref 16) is given by Eq 3 to calculate the potential change at any given depth in the casing with the applied current source being interrupted:

$$e_x = e_o \exp \left[\frac{-1.648.7(r_1)(x_1)(I_1) \exp(-x_1/L_1)}{e_o} \right] \quad (\text{Eq 3})$$

where e_o is the potential change at wellhead when applied current is momentarily interrupted (mV); e_x is the potential change at depth x_1 from the wellhead (mV); r_1 is the unit resistance of the innermost casing (Ω/m or Ω/ft); x_1 is the distance from wellhead (m or ft); I_1 is the current in the innermost casing (A); and L_1 is the length of innermost casing (m or ft).

A more sophisticated mathematical model was developed by Dabkowski (Ref 17), and a spreadsheet version was developed by Smith et al. (Ref 18).

Casing-to-Anode Separation

The spacing of the anode to the casing can also change the current required for a particular casing as illustrated by data from Blount and Bolmer (Ref 11) plotted in Fig. 11. The current requirement to protect the casing increases if the anode is brought too close to the casing. There is an optimum distance beyond which a further increase in distance is of no benefit. Hamberg et al. (Ref 7) also demonstrated a similar result in offshore well casings.

A comparison of the distribution of current in two similar casings that were 2600 m (8530 ft) (well casing "A") and 2475 m (8120 ft) (well casing "B") deep in the same area but with different casing-to-anode separations is shown in Fig. 12. The excess current being impressed onto the casing near the surface helps provide an

Fig. 11 An example of the change in current requirements with anode to well spacing. Source: Ref 11

understanding of this change in current requirement due to the casing-to-anode separation (Ref 14).

Blount and Bolmer (Ref 11) found that the anode bed should be at least 30 m (100 ft) from casings that were on the order of 1220 m (4000 ft) deep. This distance should be increased for deeper wells for optimum performance. The anode bed in either the $E \log I$ or the CPP test should therefore be located at a distance from the well casing similar to where the permanent anode bed will be installed.

Coated Casings

Coatings are available that are durable enough to withstand many of the rigors of a casing installation. Although significant coating damage is expected, Orton et al. (Ref 20) reported that the current requirement of a coated casing with bare couplings and no effort to repair coating damage can be reduced to less than 10% of that of a similar bare casing. A further benefit is that a reduction in the current requirement will also reduce the interference effects on nearby structures and casings as discussed below.

Cathodic Protection Systems

The cathodic protection system for a well casing requires the same consideration as that for a pipeline. There are two types of cathodic protection systems used for well casings and pipelines: sacrificial anode systems and

impressed-current systems (see the article "cathodic protection" in Volume 13A for additional information).

Sacrificial Anode Systems. In the early years, a sacrificial anode system was often used for wells where a low current requirement was predicted. Sacrificial anode systems are still appropriate for more shallow wells with a low current requirement.

An impressed-current cathodic protection system is the most common type for well casings due to the amount of current typically required for protection. A separate installation (Fig. 13) is common at each well. If two or more wellheads are in close proximity, interference can result (Ref 21–23).

Power Sources. Where ac power is available, it is likely that a standard or pulse-type rectifier will be used as a dc power source. Otherwise, thermoelectric generators, solar, wind-powered generators, and engine-driven generators are all possible candidates for the dc power source.

Thermoelectric generators (TEG) have a limited power availability; therefore, the anode bed resistance should be kept low to obtain the required current. The available power from a TEG usually peaks at around 0.6 to 1.2 Ω and reduces as the circuit resistance increases. The manufacturer's technical information must be consulted. A clean regulated fuel source such as natural gas or propane is required.

Both solar- and wind-generated power need batteries as a backup power source to provide cathodic protection current when there is either no sun or wind, respectively. The use of solar is

Fig. 12 An actual example of current distribution in similar casings but with different casing-to-anode distances. Source: Ref 18

less popular in the northern regions where there is a lack of sunlight in the winter, and wind power is not appropriate unless the area is historically windy.

Engine-generator systems are best used with an ac generator feeding a rectifier for dc output and control. Maintenance on dc generators has proved to be high in the past, resulting in many outages during the year. Although to a lesser degree than the dc generator, the ac generator also requires maintenance and regular inspections.

Pulse rectifiers provide a high-voltage dc pulse of short duration. The frequency of the pulse may be from 1000 to 5000 Hz, but the duty cycle is normally set in the range of 10 to 15%. Bick and Bauman (Ref 24) reported that total current requirements can be reduced to 50% or less using a pulse rectifier instead of a conventional rectifier, and more current will reach the lower portions of the casing. The improved performance is attributed to the waveform. However, Dabkowski (Ref 25) showed mathematically that the pulse from the rectifiers would attenuate to 0 at 500 to 1000 m (1640 to 3280 ft) from the casing top, suggesting that any improved performance is not due to the pulse. It has been the author's experience that cathodic protection with pulse rectifiers can be achieved down to 80% of the comparable current to a conventional rectifier, but not the significant reduction suggested by Bick and Bauman. Further work needs to be completed to validate any of these claims. The digital instrumentation measuring the pulse rectifier output is another factor in this comparison, as errors can be realized depending on the sampling rate. A major disadvantage of pulse rectifiers is noise interference, especially on communication equipment that may be servicing the well. This can be reduced by locating the pulse rectifier away from the electrical/communication building, not paralleling electrical cables, and using deep anodes.

Regardless of the power source, one negative cable must be connected to the well casing while

a second negative cable is often run to the isolated surface facilities to assist in interference mitigation.

The anode bed design and location is largely dictated by the soil layer resistivity and the location of surface facilities and pipelines. If uniform low-resistivity soil conditions exist at a surface location that is sufficiently remote from the casing and other structures, a shallow anode type of anode bed can be used. Where high-resistivity conditions exist at the surface but more suitable strata exist underneath, a deep anode bed would be preferred. The latter anode bed will also tend to reduce interference with surface facilities, as the major portion of the anode gradient exists below pipeline and foundation depth. It must be noted that the same spacing between the casing and anode must be maintained whichever type of anode bed is used, as going deeper does not change the distance between the structures.

The anode bed should be located at an equal or greater distance than the temporary anode bed to the casing that was used during the current requirement test. However, a minimum spacing of 30 m (100 ft) from the well for shallow wells but preferably greater than 50 m (165 ft) should be maintained. The separation between anodes and structures not receiving current will vary depending on the voltage gradients in the soil but should be 100 m (300 ft) or more. Otherwise, provision for interference control discussed below must be considered.

Direct-Current Stray-Current Interference

Stray current can be defined as current in an unintended path. Many sources of current use the earth as part of their electrical circuit. Conductors in the earth such as well casings and pipelines provide opportune parallel paths for current intended for another purpose.

The area of stray-current pickup is similar to cathodic protection and not of concern. However, the manner by which that current returns to its original source is of concern. Should that current *leave* the casing to enter the soil, the casing in that location is anodic and accelerated corrosion occurs.

Stray-Current Pickup. A stray current may be picked up at the surface, in which case the current must discharge into the soil downhole to return to its source. Alternately, a current discharge near the surface to either facilities near the wellhead or to the surface casing may occur, in which case there will have to be a current pickup downhole. Both cases (Fig. 14) are a cause for concern as there is a current discharge occurring at some point along the casing.

Since an electronegative shift in casing-to-soil potentials occurs with the application of cathodic protection, a stray-current pickup at a lower depth with a discharge near the surface can be detected by an electropositive shift in casing-to-electrolyte potentials, with the reference electrode located near the wellhead, when the foreign dc power source (s) is energized. Conversely, a current pickup at the surface will be detected by an electronegative shift in potentials when the foreign current source comes on. The area of current discharge will then be at a point lower on the casing, and its location would have to be defined by a CPP log, or similar.

Stray-current pickup on pipeline systems away from the well casing can result in a stray-current discharge from the well casing if the two structures are continuous. In these cases, a current pickup is normally close to the anode bed while the discharge is near the wellhead. However, it is conceivable that the current pickup and discharge points can develop at other points, especially if varying coating qualities or vastly differing resistivities exist along the pipeline or casing.

Stray-Current Sources. The stray current may come from a relatively steady-state source such as another cathodic protection system (Ref 21–23) or a high-voltage dc power line ground, or it may come from a dynamic source such as a transit system, welding machines, dc mine equipment or, finally, from telluric current that is a natural source of stray current (Ref 26).

Interference Control. Interference can be controlled by:

- Providing a metallic return path for the stray current
- Moving the offending anode bed or ground
- Adjusting the current distribution in the foreign system
- Installing and/or adjusting a cathodic protection system on the well casing to counter the stray-current effects
- Using common cathodic protection systems (Ref 21)
- Balancing wellhead potentials

A well casing cathodic protection system can also cause interference on surface facilities or

Fig. 13 Typical cathodic protection installation

pipelines. In this case, a second negative circuit is often provided in the rectifier to both control interference and assist with the protection of the surface facilities or pipelines.

Orton et al. (Ref 20) reported that a coated casing reduced the cathodic protection current requirement to 10% of a bare well casing. This in turn will reduce the tendency for mutual interference of nearby casings.

Isolation of Well Casings

The purpose of isolating a well casing from surface facilities is twofold: (a) it eliminates a macrocorrosion cell between the casing and the surface facilities, and (b) it allows the cathodic protection current distribution to be controlled between the well casing and the surface facilities.

In addition, an isolating feature allows the current impressed on the well casing to be directly measured in the connecting cable. If not isolated, a means of measuring the current return from the casing itself must be established, such as a clamp-on ammeter around the wellhead at the surface, to confirm that the "current" criterion is being met.

From a cathodic protection standpoint, the preferred location for this isolation is at the wellhead. However, some operators locate it a distance away in the event of a fire at the well so that the isolating material does not melt and complicate firefighting procedures. All tubing conduits and pipe supports must also be isolated if they are bypassing the isolating feature.

If the product from the well contains a large amount of brine, there is a risk of "internal" interference. This occurs where current picked up on the opposite side of the isolation uses the brine as a path around the isolation. In such a case, corrosion is seen only on one side of the isolating feature (Fig. 15A).

A "long-path" isolation, which consists of an isolating feature and an internally coated or lined section of pipe (Fig. 15B), can be used to reduce the internal interference. If this is not effective in controlling internal interference, the isolating feature should be omitted.

Commissioning and Monitoring

Inspection. A cathodic protection system must operate continuously to be effective. Regular inspection of the dc power supply to ensure that the required current is being provided in all circuits is necessary throughout the year. A more detailed inspection should be conducted annually. A description of the cathodic protection system operation and the records is given in NACE RP0186 (Ref 4).

Inspections of the dc power source should only be made by persons who are trained and qualified to work on electrical equipment. The use of strict safety practices including lockout/tagout procedures is especially necessary when working

Fig. 14 Direct-current stray-current interference. (a) Stray-current pickup near top with discharge downhole. (b) Stray-current pickup downhole with discharge near top. CP, cathodic protection

(a) Internal stray current interference through brine path across isolating fitting

Fig. 15 (a) Internal interference across an isolating feature and (b) reduced by a long-path isolating feature

on the rectifiers. The routine readings should include these measurements:

- dc power source current output
- dc power source voltage output
- dc power source adjustment setting (tap setting if applicable)
- dc current in secondary circuits
- dc interference control devices
- Power meter or fuel supply where applicable

The annual inspection should include:

- Completion inspection of the dc power source
 - (a) Calibration of the dc power source current output
 - (b) Calibration of the dc power source voltage output
 - (c) Direct-current power source adjustment setting (tap setting if applicable)
 - (d) Calibration of the dc in secondary circuits
- Measurement of the well-to-electrolyte potential
- Measurement of the surface facility structure-to-electrolyte potentials
- Testing the effectiveness of wellhead isolation, if applicable
- Measurement of the current returning from the casing at the wellhead with a clamp-on ammeter, if there is no isolation
- Confirmation that dc interference control devices are providing the necessary control
- Specialty tests applicable to the specific cathodic protection installation

Corrosion-control records are of paramount importance in an effective corrosion-control program. They will be used to establish a need for enhancements of the corrosion-control program and to ensure that the existing corrosion-control equipment is operating. The records should include but not be limited to:

Historical:

- Well completion data including casing sizes and lengths, cementing information and well total depth
- Corrosion leaks identifying well, depth, internal or external, date of failure compared to date of drilling and/or workover (s)
- Inspections of casing failures and corrosion products
- Electrical well logs (wall thickness, CPP identifying corrosion, and resistivity)
- Coating type and thickness, if applicable
- Drawing of well casing strings and lease equipment and piping
- System map of the field
- Location and type of electrical isolation

Cathodic Protection:

- Current requirement tests (CPP log(s), $E \log I$ test(s), and soil resistivity in layers near the surface)
- Design and drawings of cathodic protection installation detailing:
 - (a) Well location
 - (b) Piping and lease facilities

- (c) dc power source type, rating and location
- (d) Description of energy supply for dc power source
- (e) Cable type(s) and location
- (f) Cable to wellhead and piping connections
- (g) Anode beds type and location
- (h) Anode material type, spacing and depth
- (i) Backfill type and amount
- (j) Junction box and test station details

Interference Control:

- Records of all tests pertaining to interference on the well from other systems and on other systems from the well cathodic protection system
- List of owners and contacts involved in the interference control program
- Description of the method of interference mitigation, including control devices and target values of current and potential
- If bonds or directional devices are used, the location, type, resistance value, current, and current direction

All records must show the date, the name of the inspector or tester and, if different, the names of those who make recommendations. Any changes in current output must be correlated with other measurements taken.

Cathodic Protection Summary

For new wells, the use of an abrasion-resistant underground coating on those portions of the casing exposed to the strata should be considered as part of a corrosion-control program, as this will greatly reduce the amount of cathodic protection current required for protection. If coating is used, though, a cathodic protection system must be planned and implemented immediately, as a coating alone will concentrate corrosion at the coating holidays.

Prior to applying cathodic protection, a review of the existing well historical data should be made to assess the possibility of corrosion that will cause premature and costly failure repairs. Electrical logging tools, which are reasonably accurate, are available to assess the metal loss that has occurred and to predict the possibility of future corrosion.

Provided the proper amount of current is applied and maintained, cathodic protection of well casings has proved to be an effective means of minimizing corrosion on the casing. The cathodic protection current can be determined by various means; however, two of the more reliable results have to date been with CPP type of testing and polarization tests ($E \log I$). The former test is difficult to perform in that the well has to be taken out of service, which usually results in few candidate wells in an older field. Also it may be necessary to perform multiple tests, with time provided between tests to allow for steady-state conditions to be achieved, which adds to the cost of the test. The $E \log I$ test must be correctly analyzed to identify the Tafel point on the profile; otherwise, a current less than that necessary

may be defined as the criterion. Another option is to use a mathematical model; however, the validity of this option should be confirmed by tests at the start of the cathodic protection program.

Another factor in designing well casing cathodic protection systems is to remember that the amount of cathodic protection current required is also dependent on the spacing between the casing and the anodes, up to a certain distance, and that distance must be defined for each well. If the anodes are placed within that distance, the current requirement increases. Once a cathodic protection current requirement is established for a temporary anode bed, the same distance or greater should be used in the final cathodic protection design.

Isolation of the casing from other facilities is another important cathodic protection system design consideration. Isolating the well casing from surface facilities is preferred to eliminate the macrocorrosion cell between the casing and these structures without cathodic protection and to provide a means for controlling and measuring the cathodic protection current to the casing. However, if the product inside the isolation contains a large quantity of brine, either a "long-path" isolating fitting should be used to minimize internal interference, or in some cases the isolator may have to be removed entirely.

Generally, cathodic protection systems using conventional rectifiers are designed and installed for the protection of the casings, although pulse rectifiers have also been used. Particular attention has to be placed on the size and the location of the anode bed in order to achieve the required current output for the desired life of the anode bed.

Stray current must also be considered during the cathodic protection system design. Stray-current interference from other dc power sources will accelerate corrosion on the casing if it encourages a current discharge into the formation. A common source is from other cathodic protection systems in the same oil/gas field, but can also come from other sources not related to the oil/gas field. Several methods have been outlined to either avoid or minimize these interference effects. Any stray-current control device must be continuously inspected and maintained.

Detailed records must be kept on the history of the well, electrical logs, casing repairs, and on the operation of the corrosion-control equipment. These records must be able to stand up to future legal scrutiny.

Stray Currents in Underground Corrosion

W. Brian Holtsbaum, CC Technologies Canada Ltd.

STRAY CURRENT can be defined as a current in an unintended path. In this case, it applies to stray electrical currents in structures that are underground or immersed in an electrolyte. Stray current can be from man-made sources or from natural sources (telluric). A dc stray current discharge will accelerate corrosion on a structure where a positive current leaves the structure to enter the earth or an electrolyte. Stray alternating current at high densities will also cause corrosion, although at a much lower rate than for dc stray current.

In addition to the consequences of accelerated corrosion, stray current corrupts the potential measurements that are being taken to establish a cathodic protection (CP) criterion.

Early stray current sources came from electric street railways. The first documented occurrence (Ref 1) in 1894 was due to a direct current (dc) powered railway installed in Richmond, VA, in 1888. In Boston, MA, during 1892, a negative cable laid between the tracks was bonded frequently to a parallel water main as the first documented attempt to stop stray-current corrosion. Unfortunately, this did not work so operators tried the opposite polarity with more disastrous effects because both the cable and pipe then corroded. Litigation against the transit operators followed in 1900, and the judgment found in favor of the claimant, with the courts limiting stray-current leakage.

The American Committee on Electrolysis was started in 1913 and published a comprehensive report in 1921, after which it became inactive. Local electrolysis committees were formed as early as 1913 to 1917 (Ref 2) to address the issue. Drainage of streetcar stray currents was practiced in Belgium beginning in 1932 (Ref 3). This practice was also recognized in Germany based on a report in 1939. With the increase in industrialization, other sources of stray current also became an issue, and today it has become a problem that is automatically reviewed in underground or immersed structures. As problems are resolved, the interest in electrolysis committees decreases, but several committees still exist to resolve problems from many different stray-current sources.

Principles of Stray Current

The basic electrical laws apply to stray current including, but not limited to:

- A closed electrical circuit must exist, especially as it applies to a parallel electrical circuit.
- Ohm's law relating to voltage, current, and resistance
- Direct current can go in only one direction in a conductor.
- Kirchoff's current law, where the sum of the current at a junction is equal to zero
- Faraday's law of metal weight loss related to current and time

Stray current applies to a parallel electrical circuit where the structure is a parallel path within another electrical circuit as depicted in Fig. 1. The point of current pickup in Fig. 1 is indicated by "A," while the point of discharge is at "B" and may be either a metallic or electrolytic path to a structure.

When a current approaches or leaves a buried or immersed structure, a voltage gradient is established around the structure that is dependent on the resistivity of the electrolyte and the amount of current (Ref 3). Equipotential lines perpendicular to the direction of current can be measured around the structure as illustrated in Fig. 2 and 3. If the gradient is negative with respect to remote earth, a cathodic gradient

exists. An anodic gradient exists when the gradient is positive with respect to remote earth.

When a structure passes through a cathodic gradient, a current discharge, often called cathodic interference, can occur (Fig. 2). This current discharge must return to its source, but in this case, the controlling factor is the cathodic gradient.

Fig. 2 Illustration of cathodic stray-current interference. CP, cathodic protection

Fig. 1 Schematic of a parallel interference path

Fig. 3 Illustration of anodic stray-current interference. CP, cathodic protection

When a structure passes through an anodic gradient, a current pickup is encouraged and is often called anodic interference (Fig. 3). Again, this current must return to its source, and the manner by which this occurs is of the most concern. Both cathodic and anodic interference can occur at the same time.

If the stray current is dc, the latter case is of utmost significance, and it is important to detect even small current values. If the stray current is alternating current (ac), then a larger current density becomes critical.

Any current source that may use the earth as a path, either intentionally or inadvertently, can be a source of stray current. These can include, but are not limited to:

- Cathodic protection (CP) (Ref 3–5)
- High voltage dc (HVDC) power lines (Ref 6)
- Transit systems (Ref 1, 7–9)
- Direct current operated mining equipment
- Electric railways
- Welding, both onshore and offshore (Ref 10)
- Electroplating or battery-charging equipment with ground faults
- Natural (telluric) current (Ref 5, 11)
- High voltage ac (HVAC) power lines (Ref 12–14)

The first two sources are steady state interference sources. The remaining sources are more of a dynamic interference as they change in magnitude and often in direction. The CP examples in Fig. 2 and 3 are of a steady state type of interference, while the transit system in Fig. 4 is an example of a dynamic stray current.

In addition to these man-made stray currents, a naturally occurring stray current (telluric) influence such structures as pipelines. Telluric current is a naturally occurring current that results from geomagnetic fluctuations in the earth (Ref 11). The earth's magnetic field is generally from north to south but does vary throughout the world as shown in Fig. 5.

This magnetic field projects into outer space where it is affected by the “solar wind” consisting of solar plasma (high-energy protons, electrons, and other subatomic particles). The sun produces a stream of solar plasma of varying intensity with bursts of short wave radiation emitted with solar flares that varies in magnitude on cycles throughout the year and over a period of years.

The telluric current associated with the geomagnetic fluctuations tends to flow in the earth's crust. Should a pipeline be installed in the area of this telluric activity, a current can either be induced onto the pipe or may enter it by conduction. The potential change may be due only to changes in the earth's potential gradient, which does not reflect a current pickup or discharge. A major problem with telluric current is the inability to collect meaningful data when assessing the status of cathodic protection on a structure.

Induced ac voltages on parallel conductors have been recognized for many years but were

originally a more common problem between communication lines and power lines. As utility corridors have become more common, power lines now occupy parallel right-of-ways with pipelines. This and the improved coatings on pipelines have resulted in induced ac voltages that are becoming an ever-increasing problem.

There has been a significant amount of study on the subject since the 1970s. The American Gas Association and the Electric Power Research Institute cosponsored a study (Ref 15) to develop a method of predicting voltages on pipelines. The Canadian Electrical Association (Ref 16) commissioned a study of problems with pipelines occupying joint-use corridors with ac transmission lines. Canadian Standards Association later issued a guide (Ref 14) for power line and pipeline owners that covers the safety of the personnel working on pipelines in the area of HVAC power lines. NACE International issued a similar recommended practice (Ref 13) dealing with this problem.

There are three mechanisms, capacitive, conductive (also called resistive), and inductive, by which voltages can be transferred to pipelines paralleling an electrical power transmission line.

Capacitive effects have to be considered on aboveground pipelines, especially those with no contact to the ground such as when pipelines are under construction and on skids. The problem becomes more severe as welding increases the length of the aboveground section of pipe. Precautionary measures are covered in Ref 15 and 16.

A conductive, or resistive, coupling takes place through the soil when a pipeline is in proximity to a power transmission line ground. If large fault currents or lightning strikes on the transmission line create a large ground fault current, it can enter the pipe. It will not only cause large potential gradients for the short duration of the fault, but it may cause damage to the pipe and/or coating if it enters at a high current density. Research (Ref 14) indicated that not only can molten pits occur, but cracks can develop around the molten area (assuming that penetration has not taken place).

An inductive coupling is caused by the changing magnetic field from the ac flow in the power transmission line and different distances to each phase conductor. An ac voltage will be induced on a pipeline in the vicinity of the power line,

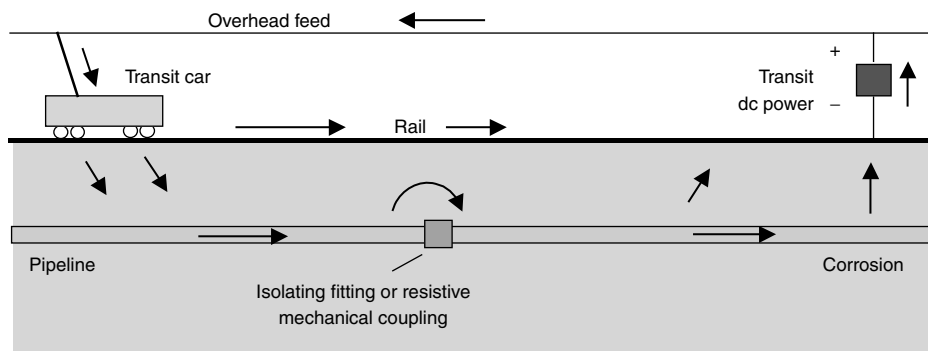

Fig. 4 Example of dynamic interference from a transit system

Fig. 5 World isomagnetic chart. Source: Ref 5

which passes through this changing magnetic field. These voltages will be essentially permanent on the pipeline but will vary somewhat with the actual load on the power line.

The prediction of induced ac voltages is complex and is covered in the literature (Ref 13). The voltage will peak at discontinuities between the pipeline and the power line and attenuate exponentially between the discontinuities to the point that portions of the pipeline may have little or no induced voltage. Discontinuities between the power line and the pipeline may be:

- A change in the transmission line to pipeline separation
- The end or beginning of the parallel exposure
- A change in the number of line conductors or pipelines in the common right-of-way

A parallel length between the discontinuities is necessary for an induced voltage on the pipeline. The better insulated the pipe is from the ground, which occurs with more effective pipeline coatings, the higher the induced voltage will be as low resistance grounding would reduce this voltage.

Discontinuities due to changes in the pipeline characteristics are sometimes more difficult to determine because the information is not readily apparent from drawings or file information. Changes in the characteristics can arise from any of the following reasons:

- A change in the coating conductivity
- An extreme change in soil resistivity (somewhat dependent on coating)
- A change in the pipe size or thickness
- An interruption in the pipe continuity (isolating features)

The most influential factors are the phase currents and their relative magnitudes, the length of the parallel section between the pipeline and power line, and the distance between the conductors and the pipeline in the relationship shown in Eq 1:

$$V_{ac} = f[I_{ac}, L, \frac{1}{D}] \quad (\text{Eq 1})$$

where V_{ac} is the induced ac voltage, I_{ac} is the phase current, L is the length of parallel section, and D is the distance between conductor(s) and pipeline (note this may not apply in proximity of power line as voltage increases initially before decreasing in the perpendicular direction from the power line).

Consequences of Stray Current

A dc discharge from a metal into an electrolyte, such as illustrated in Fig. 2, causes corrosion at the following rates for these metals:

Iron	9.2 kg/A-yr (20 lb/A-yr)
Copper	10.4 kg/A-yr (23 lb/A-yr)
Lead	34.5 kg/A-yr (75 lb/A-yr)

This in turn has to be related to the surface area of discharge and the wall thickness of the structure.

For example, a 150 mm (6 in.) schedule 40 pipe weighs 8.62 kg/m (18.98 lb/ft) and has a 7.11 mm (0.280 in.) wall thickness. This suggests that in just over one year, a 1 A current discharging from a meter of this pipe would completely consume it. If a current of only 1 mA was discharged from a 10 mm (0.394 in.) diameter coating holiday on this pipe, it would likely leak in less than 7 weeks. Immediate action is therefore required whenever a stray-current effect is noted.

Although no corrosion occurs at the point of current pickup, this current must return to its source and therefore the area(s) where this current leaves the structure (Fig. 3) must be considered as the consequences will be similar to those described previously.

There also appears to be a relationship with ac and corrosion; however, it is not as well defined as that for dc (Ref 12). At a current density less than $20 \text{ A}_{ac}/\text{m}^2$, it appears that CP is able to control corrosion. Between $20 \text{ A}_{ac}/\text{m}^2$ and $100 \text{ A}_{ac}/\text{m}^2$ ($1.86 \text{ A}_{ac}/\text{ft}^2$ and $9.29 \text{ A}_{ac}/\text{ft}^2$) corrosion is unpredictable, but at greater than $100 \text{ A}_{ac}/\text{m}^2$ ($9.29 \text{ A}_{ac}/\text{ft}^2$), corrosion can be expected.

Interference from steady state current sources will result in a current discharge and pickup at consistent locations. Dynamic interference sources that change both in magnitude and direction will continually change the locations of current pickup and discharge. Expected locations of current discharge are at areas where the structure is in a high cathodic gradient such as at a pipeline crossing, across poor continuity joints, across an isolating flange, or between isolated reinforcing steel.

An exception to stray current causing corrosion is when a structure is receiving adequate CP and has formed hydroxyl ions. The oxidation reaction may involve the oxidation of these hydroxyl ions to oxygen and water without involving the metal atoms.

Interference Tests

Current Mapping. Where it is possible to trace the stray current by a current mapping process, the location of current pickup and discharge can be determined readily. Current was measured at points in a pipeline in Fig. 6. By Kirchhoff's current law, the sum of the current at a junction must equal zero. At junction A, the current increases from 0.5 A to 1.0 A; therefore, a current pickup of 0.5 A took place in between the pipeline measurements. The current reduced after junction B; therefore, a current discharge occurred in between. The current is in opposite

Fig. 6 Current mapping of a pipeline

directions at junction D; therefore, the entire amount had to discharge at that location. There was no change in pipeline current at junctions C and E; therefore, there was no current pickup or discharge at those locations.

These current values measured in the pipeline can be plotted on a graph as shown in Fig. 7, where the current going in the opposite direction is given a negative value. The bars are the actual current pickup and discharge in this figure. The current discharge and pickup sections can readily be noted by the pipeline current profile. A positive slope indicates a current pickup and a negative slope indicates a current discharge.

A second type of current mapping can be used where the current in the soil is determined by measuring the voltage gradient caused by the current in the soil (Ref 17). This is illustrated in Fig. 8. The data are then processed by a computer program to show the variations in stray current at any given location compared with another.

Structure-to-Electrolyte Potentials. If the source of the stray current can be interrupted, a shift in the structure-to-electrolyte potential will occur at the point of exposure. The shift will be in an electropositive direction if there is a current pickup and in an electropositive direction if there is a current discharge. Both shifts are of concern.

Combination of Current and Potentials.

Where possible, a combination of both line current and potentials can be compared at different locations. Such procedures are often used for a dynamic stray-current situation, as in the transit system shown in Fig. 9, and are often called beta curves (Ref 18). In the past, the use of x - y plotters was popular, but data loggers are now more commonly used to gather data under these conditions.

The current in the pipeline at different locations can be determined by a current span as shown in Fig. 9, or by a clamp-on ammeter. The current at a given point in time can be plotted as shown in Fig. 10. Knowing the direction of current, the sections of current pickup and discharge can be determined. The current over a period of time at one location, however, will vary, in which case the current at one location can be plotted against the current at the next location over a given time period. Knowing the current direction, the slope of the line will indicate a current pickup ($<45^\circ$), no

Fig. 7 Plot of pipeline current from Fig. 6

pickup/discharge (45°), or current discharge ($>45^\circ$), as shown in the top of Fig. 11.

The next technique is an exposure survey in which the pipe-to-electrolyte potential is measured simultaneously with the current measured above. In this case, a current pickup is expected to correspond to an electronegative shift in potentials, or a current discharge corresponds to an electropositive shift in potentials. A plot of current against potential at each location will indicate a current pickup by a positive slope and a current discharge by a negative slope and the point of maximum exposure (Fig. 11). A near vertical slope suggests that there was neither a prevalent current pickup nor discharge.

A mutual survey is conducted by the measurement of the voltage between the interfering structure and the interfered structure and compared with the pipe-to-electrolyte potential measured at the same time. Correlation is indicated by a straight line on a plot of these measurements. This measurement does not reveal all points of current discharge but averages the condition between the measurement locations.

Telluric Current. For best results in potential measurement, it is desirable to wait for a quiet period of solar activity and complete the survey at that time. Before measuring pipe-to-electrolyte potentials, a geomagnetic forecast that is available throughout the world should be checked.

If a survey must be conducted in periods of high solar activity, special testing and compensation of measurements are necessary. One fundamental type of telluric survey involves the continuous measurement of structure-to-electrolyte potentials with a data logger at stationary locations within the test sections and the recording of structure-to-electrolyte potentials with a portable data logger that is time stamped with the stationary data loggers.

The data in Fig. 12 were obtained by a data logger and show the effects of telluric current at three different locations on a fusion bonded epoxy coated pipeline. One is approximately 2 km (1.24 miles) from the first, while the second is approximately 57 km (35 miles) away. The significance in this profile is that the potential variations are similar over time along a large

section of well-coated pipe. If the potential at one location can be established, then by extrapolation, the potential at other locations can also be determined.

Another study (Ref 18) showed similar voltage fluctuations on two different gas distribution systems that were owned by different companies 700 km (435 miles) apart. This information was detected by remote monitoring potential equipment that has only recently been used. Heretofore, the belief was that telluric current primarily affected pipelines longer than 50 km (30 miles) in length. This new information shows that pipelines less than 5 km (3 miles) in length can also be affected. In addition, the area of influence due to this activity can be very large, and similar effects can be seen on completely separate systems.

Once the true potential at the stationary locations has been established, the true potential at the portable location can be approximated using Eq 2 and 3:

$$eb = \left[\frac{ea(c-b)}{c} \right] + \left[\frac{ec(b-a)}{c} \right] \quad (\text{Eq 2})$$

where a is the first stationary potential location, b is the portable potential location, c is the second stationary potential location, ea is the error in potential at stationary data logger "a" at time "x," eb is the error in potential at portable data logger "b" at time "x," and ec is the error in potential at stationary data logger "c" at time "x."

Equation 2 then applies the correction to the measured potential at the portable data logger's location:

$$E_{p \text{ true}} = E_{p \text{ measured}} - eb \quad (\text{Eq 3})$$

where $E_{p \text{ true}}$ is the true potential at the portable data logger location, $E_{p \text{ measured}}$ is the measured potential at the portable data logger location, and eb is the error in potential at portable data logger location.

If the potential closely follows that of the nearby stationary data logger position, then correcting only to the closest stationary data logger location would be accurate. Equation 4 is then used to compensate the measured potential in this case:

$$E_p - E_s - \Delta(E_{sa} - E_{pa}) \quad (\text{Eq 4})$$

where E_p is the true potential at the portable data logger location, E_s is the true potential at the

Fig. 8 Current mapping of stray current at a buried pipeline. Source: Ref 7

Fig. 9 Potential and current tests on a dc transit system

Current and direction shown above at a given time

Fig. 10 Relationship of line current and direction

stationary location, E_{sa} is the stationary potential at time “a” during the data logging, and E_{pa} is the portable potential at time “a” during the data logging.

Hazardous ac Voltages. Alternating current voltages can occur on pipelines that parallel HVAC power lines by either a capacitive, inductive, or conductive coupling. The inductive coupling is relatively steady state and is the ac voltage normally measured.

A measurement of the ac voltage to ground can be made in a similar manner as a dc structure-to-electrolyte potential except that an ac voltmeter must be used, and the type of reference electrode is not critical. A major difference is that the ac voltage will vary over short periods of time depending on the power line load as illustrated in Fig. 13. A single measurement of the ac voltage on the pipeline may not reflect the most hazardous condition.

Figure 13 also demonstrates the effect of a grounding, but the resistance to ground was still not low enough to bring the voltages down to below 15 V_{ac} (Ref 13, 14) that is considered safe on the pipeline.

An explosion resulting from ac interference has been documented (Ref 19). The safety of the operating personnel and the public is the basis for attempting to predict and mitigate hazardous situations, which may arise when ac voltages are transferred to a pipeline.

Visual Inspection. The first indication of dc stray current may be by a visual inspection of corrosion. Stray current can be suspected by a lack of corrosion product and by its physical location. Corrosion at a pipeline crossing, near an isolating feature, or on one side of a mechanical joint are suspect.

Internal dc stray current interference may occur on one side of an isolating feature

where there is a low resistivity product inside (Ref 20).

Mitigation

Eliminate or Minimize Source of Stray Current. The most effective means of controlling stray current is to relocate or reduce the exposure. The approach is unique for each exposure. Examples include:

- Anodic interference can be removed by relocating the anode bed or structure or by redistributing the current with additional anode beds.
- Readjustment of the current at the source if possible
- Cathodic interference may be reduced by recoating the structure with the high cathodic gradient to reduce the current at that point and, therefore, the gradient.
- Transit tracks can be isolated from the earth through isolation material between the rails and the ties and in switch connections (Ref 8).
- Bonds in transit tracks to reduce the resistance of the intended current return path (Ref 7, 8)
- Repair of equipment that is faulting to ground

Control Bonds. A metallic bond that is of low-enough resistance can provide a safe path for stray current to return to its source provided the potential of the “interfering” structure is more electronegative at the point of connection (Fig. 14). If the potential is more electropositive, the additional current transferred to the “interfered” structure adds to the amount that may be discharging through the electrolyte. That is, the interference condition will be compounded.

Advantages of a mitigation bond include:

- The bond will transfer the stray current safely if the resistance is correct.
- The bond is relatively inexpensive and can usually be installed quickly.
- The bond can be monitored relatively easily.

Figure 15 shows the use of mitigation bonds on a transit system.

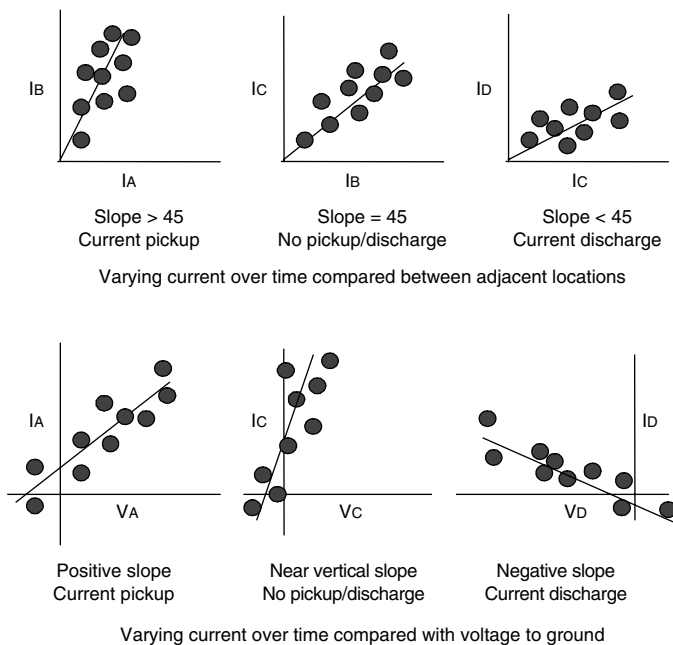

Fig. 11 Relationship of varying line current and pipe-to-electrolyte potentials over time

Fig. 12 Potentials measured with two stationary and one portable data logger at different locations along a fusion bonded epoxy-coated pipeline. Note that the Portable 1 profile is virtually identical to the Stationary profile 2 km (1.24 miles) away and similar in shape to Portable 2 profile 57 km (35 miles) away. Source: Ref 4

Fig. 13 Sample induced ac voltage on a pipe (top profile) and the effect of a temporary ground (lower profile)

Disadvantages of a mitigation bond include:

- Bonds can be destroyed by current surges.
- The bond is a critical bond and must be inspected bimonthly if on a regulated pipeline and should be monitored this frequently otherwise.
- The cathodic protection systems of the two structures become dependent on one another.
- Excessive potentials can occur before the stray current effect is controlled.
- Under dynamic stray current conditions, the potentials can reverse (see “Reverse Current Switches” subsequently).

Reverse current switches are used in a bond to allow current to go in the desired direction but to prevent a reverse current that could cause accelerated corrosion on the structure (Ref 21, 22). Ideally, a reverse current switch would have zero impedance in the direction of desired current and infinite impedance in the opposite direction and must have the capacity to control the desired amount of current.

A reverse current switch could consist of an electromagnetic relay, a diode, or a hybrid system. A potential-controlled rectifier installed in the bond can be used as a forced-current drainage bond to serve the same purpose.

An electromagnetic switch will close when sensors detect that the structure becomes more electropositive than a set point. The stray current passes through the relay contacts. The relay should open when the current passes through the zero point, which will reduce the arc burns on the contacts. The disadvantages of the relay include:

- They normally require a power source.
- They have a limited number of open/close cycles.
- They may have a slow response time relative to the changing stray-current frequency.

A diode is a solid state device that has low forward impedance with high reverse impedance. Germanium and copper oxide diodes have a low forward voltage drop and the expense of poor reverse voltage breakdown. Silicon diodes have high forward and high reverse voltage drop characteristics. A high amount of heat can be generated through a diode that must be dissipated, usually through a heat sink. Stray currents often have an ac component that will be rectified by the diode. The diode must be derated from a dc output at maximum current output, depending on the waveform.

Unfortunately, the waveform is not detected by an ammeter, thus an oscilloscope must be used to determine the phase angle. Finally, the possibility of induced ac voltages must also be considered in rating these devices. Diodes have a forward voltage drop that has to be exceeded before they conduct. This may be too great for low-voltage applications.

A hybrid system may consist of two different types of diodes (germanium and silicon) in parallel often with a resistor in series with the low forward impedance diode (germanium). This combination ensures a faster conduction, while the resistor ensures that the silicon diode will conduct more current. Another combination is a silicon diode in parallel with an electromagnetic relay. The relay can be much smaller as the diode conducts the higher current.

Another hybrid system consists of a diode in parallel with a tapless automatic potentially controlled rectifier. The rectifier can be set to conduct before the diode up to a given current after which the diode continues to carry the balance. These are custom designed to a particular application.

Cathodic Protection. It is possible that by enhancing the CP on the interfered structure, the stray current could be minimized. A sacrificial anode(s) can be installed at current discharge areas such that the discharge will go from the anode to the electrolyte. Care must be used in the location of sacrificial anodes to ensure an adequate current will discharge from them and because they could be a source of ac pickup. In one documented case, this in turn caused an explosion when the ac surge arced across an isolating flange (Ref 13).

Dividing the system into several electrical sections by installing isolation and protecting each section by independent CP systems has been used (Ref 14). This approach has to be taken very carefully because an interference problem can be established at any one of the new isolating features.

Mitigating Induced ac Voltage. Dangerous capacitive voltages can be diminished by ensuring that all aboveground pipe sections are adequately grounded. These include electrical grounds to aboveground pipelines, bonds around open sections of pipe that are attached with a bolted clamp, and temporary gradient mats attached to the pipe for personnel to work on.

Conductive or resistive couplings can be reduced by ensuring that the pipeline and electrical grounds are separated as far as possible. Canadian Standards Association (Ref 14) recommends a spacing of 10 m (33 ft). The use of temporary ground mats and bonds installed around “open” pipe sections will protect personnel.

Induced voltages can be predicted with mathematical models, and a permanent mitigation scheme can be devised that normally includes grids around above pipeline appurtenances and grounds at voltage “peaks.” It

Fig. 14 Mitigation bond showing when and when not practical

Fig. 15 Mitigation bonds for a transit system (reverse current switches often put in bond back to power supply)

Fig. 16 Alternating current voltage protection during operations. Source: Ref 16, 22

Fig. 17 Ground mat (gradient grid) at underground valve

should be noted that the reduction of a voltage peak at one location often causes an increase in voltage elsewhere.

Alternating current voltages on the pipeline in excess of 15 V_{ac} have been accepted by industry (Ref 13, 14) as being hazardous. Alternating current voltages can be mitigated by strategically placed electrical grounds to the pipeline, usually at the discontinuities. Voltages in excess of 50 V_{ac} have been measured on pipelines and that required a current drain to ground in excess of 50 A_{ac} to reduce the pipeline voltage to less than 15 V_{ac}. Direct current decouplers may be necessary in series with the ground cable to allow the passage of ac but to isolate dc and thus reduce an adverse effect of adding bare metal to the cathodic protection system.

Personnel working with CP must be trained to measure ac voltages safely because they are continuously taking electrical measurements on pipelines but expecting low voltages. A safe practice is to take the ac voltage measurement first.

Cathodic protection test stations need not have a gradient grid, but their terminals should be protected to prevent accidental contact from the public, and pipeline personnel need to be trained accordingly.

Pipeline personnel working in these areas need to be trained properly in the hazards of ac voltage on pipelines and the necessary safety procedures to include in maintenance, excavations, and repairs (Fig. 16). This is particularly important on the well-coated pipelines that are

more common today. In addition, personnel contacting pipeline appurtenances within 20 km (12 miles) of an HVAC parallel section should be protected by the installation of a gradient grid around it (Fig. 17).

Where a dc isolation is required but an ac connection is necessary, a dc decoupler can be inserted in the bond. These can be in the form of an electrolytic polarization cell or an electronic decoupler. These allow dc to be maintained for CP while reducing ac voltage to a safe level.

Corrosion Rate Probes for Soil Environments

Bernard S. Covino, Jr. and Sophie J. Bullard, National Energy Technology Laboratory

DESIGN ENGINEERS WORKING WITH BURIED OR PARTIALLY BURIED STRUCTURES must allow for the corrosion of their structures. Typical metal structures that are exposed to soil corrosion include bridge pilings, pipelines, buried storage tanks, and storage tank bottoms. Corrosion of these structures contributes significantly to the direct and indirect costs of corrosion. Direct costs include not only the damage to or the potential loss of the structure but also the costs of corrosion prevention methods such as coatings and cathodic protection. Indirect costs result when these measures fail to protect the structure and lead to a loss of or downgrading of services, such as the closure or derating of bridges or pipelines.

There is much known about the corrosivity of soil and a good general review is available in the article "Simulated Service Testing in Soil" in *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, of the *ASM Handbook* (Ref 1). Factors such as soil composition, structure and texture, soil electrical resistivity, and soil pH have been well characterized and correlated to the corrosion of metals. The American Water Works Association (AWWA) standard C-105 for Soil Corrosivity (Ref 2) assigns numerical values to different levels of resistivity, pH, redox potential, sulfides, and moisture in order to predict the level of corrosion in soils. At the present time, however, most of the information on the corrosion of metals in soils is acquired through gravimetric measurements of buried test specimens. Such tests typically yield accurate information on the corrosion rate of the specimen in one particular soil but only for a fixed period of time.

There are, however, times when it is important to know what has happened between the time mass loss specimens are buried and when they are retrieved. In other words, how does the corrosion of metals in soils change with time or how is it influenced by other factors? One way to do this is to use sensors or probes coupled with an appropriate technique for measurement of the corrosion behavior of the specimen in soil. Another use for soil corrosion rate sensors is to measure the relative changes in soil corrosivity

with time. This may be used to determine, for example, when water levels or soil compositions change.

This article explores the use of several techniques for measuring the corrosion behavior of buried metals and the types of probes that were used. The discussion is divided between electrochemical and nonelectrochemical techniques for measuring the corrosion rates of buried probes. Principles of operation for all of the corrosion measuring techniques are covered first, followed by examples of their use from literature reports. Descriptions of the principles of operation of the techniques are brief because all have been well explained in the literature (Ref 3) and in the article "Methods for Determining Aqueous Corrosion Reaction Rates" in *Corrosion: Fundamentals, Testing, and Protection*, Vol 13A, of the *ASM Handbook* (Ref 4).

Nonelectrochemical Techniques—Principles of Operation

Electrical Resistance. The electrical resistance (ER) technique is the main nonelectrochemical technique used for measuring corrosion rate. It uses the electrical resistance of a thin piece of a metal test specimen as the sensor to monitor the loss of metal due to corrosion. For some applications, the sensor must be relatively

thin in order to have sensitivity that is adequate to measure small changes in corrosion rate. This can lead to short sensor lifetimes. The principle of operation is that as the piece of metal becomes thinner, the resistance of the metal increases. While knowledge of the specific resistivity of the metal may be needed to calculate the change in thickness of the metal as the ER changes, the use of a half-bridge configuration can make that unnecessary. The half-bridge measurement configuration is used to provide temperature compensation, and it also removes resistivity from the calculation giving the change in area directly. Knowledge of the atomic mass and density of the metal then allows for the calculation of a mass change and, ultimately, a corrosion rate. The ER technique functions the same regardless of the corrosion mechanism and will give a constant readout of the gross change in cross-sectional area as a function of time. Note that the ER technique does not function well in pitting environments because corrosion pits could be interpreted as thinning of the sensor cross-sectional area and thus as a uniform corrosion rate.

Figure 1 shows a common configuration for a multiuse ER probe. The fixed-length ER probe has a wire, tube, or strip loop element of fixed length. While not configured for deep soil use, this probe can be adapted or reconfigured for those uses. Figure 2 shows a surface strip element ER probe that is more appropriate for

Fig. 1 Fixed-length electrical response probe schematic. Dimensions given in inches. IL, insertion length. NPT, American National Standard Taper Pipe Thread. Source: Metal Samples, Munford, AL

monitoring of underground pipelines and other structures. As shown, it includes a grounding wire for connection to a structure that is under cathodic protection (CP).

Electrochemical Techniques—Principles of Operation

In the context of the discussion in this article, electrochemical techniques are defined as those techniques that are able to measure the rate of one or more of the electrochemical reactions that are part of the corrosion process. While most electrochemical techniques are developed and first used in aqueous solutions in laboratories, many are applied in the field and used in soils and concrete. Many of the following techniques have been discussed elsewhere (Ref 4).

The linear polarization resistance (LPR) technique is based on the polarization of a test specimen in both the anodic and cathodic directions within ± 20 mV of the open circuit corrosion potential (OCP). The LPR technique makes use of a simplification of the Butler-Volmer equation by Stern and Geary that results in the equation:

$$R_p = \frac{\Delta E}{\Delta i} = \frac{\beta_a \beta_c}{2.303(i_{\text{corr}})(\beta_a + \beta_c)} = \frac{B}{i_{\text{corr}}} \quad (\text{Eq 1})$$

where R_p is a resistance obtained from the LPR and electrochemical impedance spectroscopy

Fig. 2 Surface strip electrical resistance probe schematic. Source: Metal Samples, Munford, AL

Fig. 3 Three-electrode linear polarization resistance probe schematic. Dimensions given in inches. IL, insertion length. NPT, American National Standard Taper Pipe Thread. Source: Metal Samples, Munford, AL

(EIS) techniques; ΔE and Δi are the changes in potential and current density that are caused by applying either a potential or current, respectively; B is the Stern-Geary constant; β_a and β_c are the anodic and cathodic Tafel constants, respectively; and i_{corr} is the corrosion current density from which a corrosion rate may be calculated.

A typical three-electrode LPR probe is shown in Fig. 3. As configured here, the three electrodes are cylindrical and of equal surface area. This type of probe can be used equally well with most of the other electrochemical measurement techniques discussed subsequently (except for hydrogen permeation and potential probe).

Electrochemical Noise (EN). The EN technique involves the measurement of spontaneous changes in current and potential due to natural variations in the corrosion current and the corrosion potential. The corrosion rate is estimated from the resistance noise, R_n . Instability in the corrosion processes due to localized corrosion can also be identified by the technique. For this form of localized corrosion, the risk of pitting on the metal surface is derived from the EN and the harmonic distortion analysis (HDA) data. This value is termed the pitting factor (PF). The PF, which is calculated from the ratio of the standard deviation of the EN corrosion current divided by the average corrosion current from the LPR technique, refers to the risk of localized attack (pitting) on the metal surface and is always examined together with corrosion rate. The PF has a value between 0 and 1. Values of $PF < 0.1$ indicate a low probability of pitting. For $PF = 0.1$ to 1, the system will be in a pitting regime rather than a regime of general corrosion.

Harmonic distortion analysis (Ref 5) is an extension of the LPR technique that uses a low-amplitude, low-frequency sine wave to polarize the electrodes. Its use allows for the measurement of an HDA corrosion rate and, more importantly, the measurement of the Tafel constants, β_a and β_c , and the calculation of B , the Stern-Geary constant.

Electrochemical impedance spectroscopy involves the analysis of the impedance of a corroding metal as a function of frequency. Analysis of the data focuses on determining a

value of the charge transfer resistance that is analogous to the polarization resistance (Ref 3). This technique also uses Eq 1 to calculate corrosion rate.

Galvanic current probes rely on the difference in corrosion potential between two dissimilar metals that are coupled together through a zero-resistance ammeter (ZRA) as shown in Fig. 4. Typically, the more noble metal becomes the cathode and the more active metal becomes the anode. If it is important to match one part of the probe couple to the structure of interest, it would be best to make the structure's metal the anode. While it may be difficult to find a couple that would simulate the corrosion of the structure and give quantitative corrosion rates for the structure, a more likely use would be to use the galvanic current probe as a qualitative indicator of soil corrosivity.

A recently developed multielectrode array corrosion probe (Ref 7, 8) measures a coupling current across a resistor placed between any two sensors in the array. The sensors are of identical composition, which would normally lead to no coupling current unless the sensors are in different environments or are experiencing different types or levels of corrosion. While individual corrosion currents can be measured for each pair of sensors in the array, it is the cumulative corrosion rate for the entire probe that would be used to monitor corrosion in soils.

The hydrogen permeation technique is used to detect the amount of hydrogen diffusing through a metal membrane. This hydrogen is typically produced by the corrosion reaction or by metal charging operations such as cathodic protection. While it is not always used to measure corrosion rate, it can be used to study soil corrosion as one investigator (Ref 9) did. He used it to attempt to measure the presence of microbiologically influenced corrosion.

Potential probes are sometimes used to assess the qualitative corrosion state of structures but cannot be used to measure corrosion rates.

Fig. 4 Galvanic probe. Source: Ref 6

These are not discussed further because they are outside the scope of this article.

Nonelectrochemical Techniques— Examples of Uses in Soils

The ER technique was coupled to a thin film resistance probe to measure the corrosion rate of an underground pipeline (Ref 10). The corrosion probe consisted of a 1 μm thick carbon steel layer deposited onto a glass substrate and is shown as configured in Fig. 5. A titanium dioxide (TiO_2) interlayer was used to improve the adhesion of the steel to the glass. The final probe configuration consisted of two ER probes and one mass loss coupon. One of the drawbacks of this probe is that it could have a short lifetime due to the thin (1 μm) sensor element. Laboratory research did show, however, that the probe was responsive to corrosion rates ranging from 0.013 to 220 mm/yr (0.5 to 8660 mils/yr).

The same thin film ER probe was also used in a field test that was located near a liquefied natural gas (LNG) pipeline that had been coated with polyethylene (PE) and was cathodically protected. The corrosion rate measured by a probe that was not connected to the pipe or the CP system was 0.088 mm/yr (3.5 mils/yr), a value that was consistent with that reported for steel in soils. A probe attached to the pipeline, and thus the CP system, showed an order of magnitude lower corrosion rate, 0.008 mm/yr (0.3 mil/yr), as would be expected.

Another type of ER probe was used to determine the effectiveness of a coated underground pipeline CP system (Ref 11, 12). A recommendation for the area of the ER sensor was that it should be about the size of possible coating defects in the pipeline being monitored. For this study, that area was 25 cm^2 (3.9 in^2). The

thickness of the sensor should be appropriate to last for the design life of the pipeline. This requires some prior knowledge of the soil corrosivity, and for this study led to the selection of 0.64 mm (25 mils) for the sensor thickness for this probe. At one of the test sites the corrosion rate measured for the unprotected probe was 71 $\mu\text{m}/\text{yr}$ (2.8 mils/yr) and 5 $\mu\text{m}/\text{yr}$ (0.2 mil/yr) when the probe was connected to the CP system. Recommendations from this study (Ref 12) were that a minimum of 12 months monitoring was necessary in order to observe corrosion rate trends.

A specially constructed ER probe, made using a high molecular weight polymer with continuous micropores to absorb water, was used to measure soil moisture content (Ref 13). Soil moisture can cause decreases in soil resistivity, resulting in higher corrosion rates. This probe was found to work well in loam soils with 10 to 60% moisture.

A series of 20 ER probes were used at eight different stations of a PE-coated ductile iron pipeline (Ref 2). These probes were used in clean sand fill and in native soil. Probes were used both under and above the PE coating in the ungrounded (i.e., not connected to the pipe), grounded, and grounded and cathodically protected configurations. The ungrounded ER probes were observed to correctly predict the low corrosion rates under the PE coating and the lower corrosion rates in the clean fill as opposed to native soil. Problems occurred, however, when grounded probes had anomalously high corrosion rates, probably due to galvanic effects from the different compositions of the steel probes and the ductile iron pipe. A suggestion by the authors (Ref 2) was to use probes with the same composition as the equipment being monitored and to use ER probe corrosion rates in a comparative rather than absolute mode.

Electrochemical Techniques— Examples of Uses in Soils

Several investigators have designed and used multisensor probes (Ref 9, 14–18) (Fig. 6). Many were modifications or improvements (Ref 9, 14–16) on the original Novaprobe (Ref 17). Common features of these types of probes is that some include sensors for measuring hydrogen absorption, resistivity, and open circuit potential (OCP). They also typically include three sensors for using techniques such as LPR, EIS, Tafel, galvanostatic, and pulse. The Novaprobe (Ref 17) used only soil resistivity, soil redox potential, and pipe to soil potential to characterize corrosion susceptibility, not corrosion rate.

In addition to LPR and EIS corrosion rate measurements, one of the multisensor probes (Ref 14, 15) was used to detect sulfate-reducing bacteria (SRB) activity. Large electrode capacitances (Ref 9) measured with EIS were interpreted to indicate the formation of porous iron sulfide scales during SRB corrosion. This has the possibility of being used as a SRB indicator. Hydrogen permeation measurements were used to evaluate the risk of hydrogen-assisted stress-corrosion cracking.

Another version of the multisensor probe (Ref 16) was used with EIS as the main corrosion measurement technique. With that probe/technique combination, the investigators were able to rank the soil corrosivity at four different test sites with fair agreement between the electrochemically determined corrosion rates and those of mass loss coupons. The electrochemical corrosion rates varied from 1.3×10^{-2} to 3.3×10^{-2} $\text{g}/\text{m}^2 \cdot \text{h}$ compared with 3.4×10^{-2} to 5.5×10^{-2} $\text{g}/\text{m}^2 \cdot \text{h}$ for mass loss coupons.

Fig. 8 Soil test cell with three corrosion electrodes and four resistivity electrodes

Fig. 9 Soil corrosion electrodes used in the soil test cell in Fig. 8.

A modified Novaprobe was coupled with EIS to measure soil corrosion rates (Ref 18). Investigators preferred the EIS technique over other electrochemical techniques because of the following reasons: (a) the EIS technique is non-destructive because the 10 mV signal is not large enough to drive either the anodic or the cathodic reactions; (b) the EIS equipment can change the polarization state of the working electrode from freely corroding to anodic or cathodic while measuring the corrosion rate; and (c) the measurements are instantaneous (<20 min/measurement). The EIS-determined corrosion rates gave a good correlation to OCP with corrosion rates the highest at more negative potentials (Fig. 7). Corrosion rates more than 0.025 mm/yr (1 mil/yr) occurred only where soil resistivity was less than 10,000 Ω·cm.

The EIS technique was also coupled with a probe made from sensors cut from an epoxy-coated steel pipeline (Ref 19). The necessity of having an appropriate equivalent circuit in order to interpret the EIS measurements was stressed in this investigation.

Laboratory studies of soil corrosion were conducted using the LPR/EN/HDA techniques to measure the simulated external corrosion of gas transmission pipelines (Ref 20). The test cell (Fig. 8) was a typical soil box as specified in ASTM G 57, “Field Measurement of Soil Resistivity Using the Wenner Four-Electrode Method.” Three cylindrical electrodes of X42 gas transmission pipeline steel, Fig. 9, were inserted into the soil box as the corrosion rate monitoring electrodes. Four stainless steel electrodes were inserted at and near the ends of the test cell in order to measure soil resistivity, which could then be correlated with corrosion rate. Figure 10 shows the effect of added water and soil resistivity on the corrosion of X42 gas transmission pipe cylindrical electrodes as a

Fig. 10 Effect of added water on the soil resistivity and corrosion rate of X42 steel transmission pipeline electrodes in soil + 1 wt% NaCl

Table 1 Corrosion rates in soil compared using two different techniques

Environment	Electrochemical corrosion rates		Gravimetric corrosion rates	
	mm/yr	mils/yr	mm/yr	mils/yr
Soil	0.005	0.197	0.004	0.157
Soil + 1 wt% NaCl	0.349	13.74	0.364	14.33

function of time in soil + 1 wt% NaCl. In this environment, after the addition of only 300 mL (2 wt%) additional water, the resistivity dropped from 35,000 to 10,000 Ω·cm and the corrosion rates began increasing. At approximately 2400 mL (~16 wt%) of added water, the resistivity dropped to 1000 Ω·cm and the corrosion rates became constant, possibly due to the lack of

availability of oxygen in the water-saturated soil. Data in Table 1 show a good agreement between the electrochemical corrosion rates and gravimetric corrosion rates from mass loss samples exposed at the same time. A recently completed field study of soil corrosion coupled a three electrode probe, Fig. 11, with the LPR/EN/HDA techniques (Ref 21).

This probe was made by encasing steel rod in epoxy. Three of these probes were buried at different locations: (a) between the CP anode and the protected pipeline (probe 1), (b) very near to the protected pipeline (probe 2), and (c) far from the protected pipeline (probe 3). Note that none of the soil probes were connected to the pipe or CP system. Figure 12 shows that two different tests were conducted using these probes: the first was during dry conditions (August 2003) and the second was during wet conditions (January 2004). Corrosion rates at the beginning of each test, where there was no applied CP and where pipeline potentials were the least negative, ranged from 0.02 to 0.03 mm/yr (0.79 to 1.2 mils/yr) for probes 1, 2, and 3. Figure 13 shows that the PF were on the order of 0.01 for probes 1, 2, and 3, indicating that pitting corrosion was not likely.

Galvanic corrosion rate probes (Ref 6) are claimed to be the least complicated next to mass loss coupons. Using carbon steel (CS)-stainless steel (SS) and CS-Cu galvanic pairs in the probes, the investigators showed a good correlation between galvanic current and mass loss of separate specimens (Fig. 14a, b).

Potential Sources of Interference with Corrosion Measurements

One of the concerns with measuring corrosion using any electrochemical or nonelectrochemical technique is whether there is some outside influence affecting this measurement. Stray currents from power sources and lines and electrical fields generated by CP systems are two sources of concern.

The presence of an impressed alternating current (ac) voltage on a thin film ER probe caused an increased corrosion rate despite the presence of CP (Ref 10). The ac signal varied from 1 to 4 V_{rms} and increased the corrosion rate from 0 to 0.008 mm/yr (0 to 0.31 mil/yr). The impressed ac voltage did not interfere in the measurement of the corrosion rate but rather altered the corrosion rate. The thinness of the probe allowed for the measurement of such a low corrosion rate.

The main reason for conducting the LPR/EN/HDA study (Ref 20, 21) described previously was to determine whether the electrical fields generated by CP of a pipeline caused interferences in the corrosion rate measurements. At the test site, CP was applied to a 50 mm (2 in.) diameter fusion bonded epoxy coated steel pipe using a high-silicon cast iron anode to change the pipeline potential. Electrochemical corrosion rate measurements were then made using the LPR/EN/HDA techniques at the three locations described above. Corrosion rates are shown in Fig. 12 as the pipeline potential was increased to approximately 2 V versus the copper/copper sulfate electrode. Comparing the corrosion rates before the application of CP to those at different levels of CP shows that there were no events in

Fig. 11 Three-electrode soil corrosivity probe

Fig. 12 Linear polarization resistance corrosion rates of the three soil probes (not connected to pipeline) and the pipeline potentials of the two experiments as a function of time

Fig. 13 Pitting factors of the three soil probes and the pipeline potentials of the two experiments as a function of time

the corrosion rate-time data that could be correlated to the application of CP current, the increase in CP current, or any other cause. The same is true of the PF data in Fig. 13. The conclusion is electrochemical corrosion rate probes will have no interference problems when monitoring the corrosivity of the soil near a cathodically protected pipeline when using the LPR, EN, or HDA techniques. Note that if the probes were electrically connected to the CP system, the LPR, EN, and HDA measurements would have been affected.

Both the ER technique (Ref 12) and a multi-electrode array galvanic current technique (Ref 7, 8) were used while coupled to a CP system. Corrosion rates decreased due to the CP, suggesting that neither technique was negatively affected by the presence of CP.

Summary

- A number of techniques have been identified as being suitable for monitoring corrosion in soils: the LPR, EN, HDA, ER, EIS, and galvanic current techniques.
- No interference was detected when using the LPR/EN/HDA techniques on soil corrosion probes located near cathodically protected structures.
- ER and galvanic current techniques were able to be used to measure corrosion rate of cathodically protected structures.
- Impressed ac voltages altered the corrosion rate measurements using the ER technique.

Cathodic Protection of Pipe-Type Power Transmission Cables

Adrian Santini, Con Edison of New York

PIPE-TYPE CABLES have reliably served the electric needs of large cities for many years. They are the method by which large amounts of electric power are brought into a city environment where high-voltage transmission towers cannot be constructed. These high-voltage cables are buried beneath city streets and supply power to a network of substations. In turn, the substations reduce the voltage to levels that can be used by industrial and residential customers throughout the city.

A pipe-type cable is made up of a steel pipe that contains three insulated conductors and pressurized dielectric fluid, which is used to cool the cables and maintain the integrity of their insulation.

The reliability of these cables is contingent upon all three components working together. Power cannot travel along the conductors unless the insulation is effective. The insulation cannot be effective without the pressurized fluid. The fluid cannot be pressurized unless the structural integrity of the pipe is maintained. It is for these reasons that cathodic protection (CP) is used to protect the pipe against corrosion. Failing to do so may result in dielectric fluid leaks, possible interruption of service to customers, as well as financial loss to the power transmission cable operator.

To cathodically protect a pipe-type cable, the impressed current method of cathodic protection is used. As is the case with any other buried or submerged metallic structure, it is necessary to keep its direct current (dc) potential more negative (approximately -0.5 V) than the surrounding earth. This can be accomplished by various methods, but for pipe-type cable all systems must have one thing in common. They must be capable of safely conducting high alternating current (ac) fault currents to ground. Such faults occur when the conductor comes in electrical contact with the inner surface of the pipe as a result of cable insulation failure. In such rare cases, the resultant ac fault current must be given a path to ground to protect other equipment and personnel. To do so, the pipe must be electrically continuous for its entire

length and be connected to ground at each substation.

Resistor Rectifiers

Direct current isolation and ac conduction seem to be opposing requirements, but they can both be achieved in several ways. The oldest and perhaps the most widely used method is the resistor rectifier (Fig. 1).

In this method, a resistor bar is inserted in the cable connection between the pipe and the station ground mat. A rectifier (R) is connected across this bar, impressing a dc voltage on it. The resistance of the bar is very low (typically 0.004Ω) to minimize pipe-to-ground voltage during ac faults. Therefore, the rectifier must circulate at least 125 amperes dc through R in order to obtain the required -0.5 V, pipe-to-ground. Since the station ground is connected in parallel with the resistor bar, a portion of the rectifier current will follow the ground path, be discharged from the station ground mat, travel through the earth, onto the pipe surface, and along the pipe back to the rectifier. This is the current that is actually required to protect the pipe. Unfortunately, this current will also corrode the substation ground mat and for this reason it must be minimized.

The magnitude of this current depends on the sum of the ground mat-to-ground resistance plus the resistance of the earth path plus the pipe-to-ground resistance. Since the ground mat-to-ground resistance cannot be increased and the earth resistance cannot be realistically changed, the only way to maximize the resistance of this path is to ensure that the resistance of the pipe coating is as high as practical. This is why pipe-type cable specifications often call for coating resistance values as high as $186,000 \Omega \cdot \text{m}^2$ ($2,000,000 \Omega \cdot \text{ft}^2$). At such high coating resistance, the current requirement for cathodic protection is very low. For example, at $186,000 \Omega \cdot \text{m}^2$ ($2,000,000 \Omega \cdot \text{ft}^2$), the pipe-to-ground resistance of a 25.4 cm (10 in.) pipe,

whose length is 9.66 km (6 miles), is approximately 24Ω . The current required (I_R) to shift the potential of such a structure would therefore be:

$$I_R = \frac{0.5 \text{ V}}{24 \Omega} = 0.02 \text{ A}$$

This of course is an idealized value since it does not take into account the other resistances in the earth path. However, since these other resistances are small compared with the coating resistance, the current requirement would still be very small with all resistances considered.

Note that in this example, in order to have 0.02 A traveling in the ground path, 125 A must travel through the 0.004Ω resistor to impress the same -0.5 V on it. One sees then that, in the resistor rectifier method of cathodic protection, most of the rectifier current must circulate through the resistor in order to produce the small amount of current that is actually required for CP.

Polarization Cells

If the resistor was eliminated, the rectifier could be much smaller and the number of rectifiers could be reduced. However, since the pipe must remain grounded, some other device must take the place of the resistor. This device would have to produce the same pipe-to-ground voltage drop for CP using a minimal amount of dc current, while allowing the cable to remain effectively grounded for ac fault current safety. One such device is an electrochemical device, the polarization cell (PC) (Fig. 2).

A typical PC consists of two electrodes, each composed of 14 nickel plates, immersed in a 30% solution of potassium hydroxide. Like the resistor bar, the PC is installed between the pipe and the station ground. Under normal conditions, with the rectifier turned on, dc current flows through the cell and causes a polarization film of hydrogen to be formed on the negative electrode. As this film builds, it increases resistance to

further dc flow and eventually blocks all but a small leakage (milliamperes) of dc current. At this minimum level of dc current flow, the blocking voltage for each cell is approximately 1.0 V. It should be noted that the nominal blocking voltage of the polarization cell is 1.7 V; however, this value is reduced by the varying amounts of ac current that flows from the pipe, through the cell, to ground. This ac current is induced on the pipe by the unbalance in the loads on each of the three phase conductors in the pipe-type cable. This continuous ac flow acts to either break down the polarization film or prevent it from fully forming; for this reason, the blocking voltage across a polarization cell is much closer to 1.0 V. This means that, as the rectifier output increases, there is a corresponding increase in the voltage across the cell until 1.0 V is reached. Above this value, any additional dc from the rectifier will simply flow through the cell, corrode the positive plates, and *not* increase the pipe-to-ground voltage. This is why the current flow through the cell must be monitored to ensure that it is at its minimum.

Sometimes, it is impossible to keep the voltage across the cell below 1.0 V. In such cases, more than one PC may have to be installed in series in order to achieve the required blocking voltage that will minimize dc flow through each cell.

In addition, in order to maintain the ac fault current rating of the PC, the level and specific gravity of the potassium hydroxide solution must be kept at their specified values. The plates must be periodically inspected, as well, to ensure that they have not deteriorated thereby decreasing their surface area.

Isolator-Surge Protector

The high maintenance considerations led the industry to develop other devices to serve the same function as the PC; one of these is the isolator-surge protector (ISP) (Fig. 3). The ISP is

Fig. 1 Resistor rectifier. The rectifier (R) circulates dc current through two parallel paths, the 0.004 Ω resistor bar and the ground path. I_R is the current required to cathodically protect the pipes. The three individual pipes above ground entering the substation combine underground into a single pipe containing the three conductors.

a solid-state device, and the basic circuitry is shown in Fig. 4.

During normal operations, the capacitor blocks up to 12 V dc. If the voltage goes higher than 12 V, the gate circuit will turn on one of the two thyristors depending on polarity, dc current will begin to flow, and cathodic isolation will be interrupted until the voltage again drops below 12 V. For unbalance currents of up to 90 A ac (depending on the steady-state current rating selected), the current flows through the inductor and capacitor. If the ac increases above these levels, such as would occur during fault conditions, the voltage across the capacitor would exceed 12 V at which point the thyristors will turn on alternately every one-half cycle allowing the fault current to go to ground until the fault clears. When the ISP is subjected to lightning surges, the voltage developed across the inductor rises to a value that places the surge protector into conduction, thereby diverting most of the current to ground through the surge protector.

Although the blocking voltage of the ISP is 12 V dc, this amount is also reduced by the ac unbalance current that flows from the pipe, through the ISP, to ground. However, the reduction is rarely enough to render the ISP ineffective for dc isolation.

A more important factor to consider, when designing an ISP application, is the maximum ac unbalance current that is likely to flow through the ISP. This is because, if this current exceeds the ISP rating, the thyristors will turn on, shorting out the ISP and, in effect, eliminate cathodic protection on the pipe-type cable.

Field Rectifiers

In the previous discussion on resistor rectifiers, it was shown that if the pipe-type cable were grounded through a 0.004 Ω resistor bar, a large rectifier (most of whose output would circulate through the resistor) would be needed

Fig. 2 Polarization cell. The polarization cell (PC) is an electrochemical device that blocks dc and passes ac current. It replaces the resistor bar and makes it possible to reduce the number and size of rectifiers. The three individual pipes above ground entering the substation combine underground into a single pipe containing the three conductors.

for adequate cathodic protection. If, however, polarization cells or ISPs were substituted for the resistor, this circulating current would be eliminated and the rectifier(s) would be sized only to supply the small amount of current required for cathodic protection. These rectifiers and their associated anode-groundbeds would be located in the "field" along the route of the pipe-type cable, allowing for better current distribution on the pipe surface.

These field rectifiers (Fig. 5) could also have their output current increased or decreased as required. This is not the case with resistor-rectifiers where, in order to increase the cathodic protection current, a proportional increase in the current flowing through the resistor bar would be required. In this example, this would mean that to increase the protective current from 0.02 to 0.04 A would require an additional 125 A flow through the resistor bar. For this reason, resistor-rectifiers were designed to provide minimum CP levels at each substation end of the pipe-type cable. These protection levels can only decrease as one moves farther away from the substation, even if one assumes that the coating is in excellent condition. This, of course, is never the case, and as the pipe coating expectedly deteriorates over time the cathodic protection levels decrease even further.

There is one other advantage to replacing resistor rectifiers and that is preservation of the substation ground mat. Since the resistor rectifiers use the substation ground mat as a "sacrificial" anode for discharging the required CP current, although the current is designed to be very small and the substation ground mat has a large surface area, current discharge will cause the mat to be damaged over time.

Stray Currents

Having discussed the various ways that CP can be applied to pipe-type cables, stray dc currents

Fig. 3 Isolator surge protector (ISP). The ISP is a solid-state device that blocks dc and passes ac current. It also replaces the resistor bar and requires little maintenance. The three individual pipes above ground entering the substation combine underground into a single pipe containing the three conductors.

will, almost without exception, interfere with their protection. This is because pipe-type cables operate within large cities in close proximity to dc subways, commuter railroads, and trolley lines. A “cause and effect” summary of this problem is shown in Fig. 6.

Pipe-type feeders, like other buried metallic structures, pick up stray currents because they are exposed to voltage gradients in the earth caused by I_R (voltage) drops in the running rail of dc railroads. These I_R drops cannot be eliminated because the longitudinal resistance of the running rails can never be 0. Similarly, the voltage gradients in the soil due to these I_R drops can never be eliminated because the electrical resistance of the wooden or concrete ties, which support the running rails, cannot be infinite. Although all nearby buried metallic structures pick up these stray currents, pipe-type cables

have a particular affinity for them. Their low longitudinal resistance, in effect, makes them good parallel conductors to the rails for returning these stray currents to the transit substations.

For any given voltage gradient in the earth, the amount of strays picked up depends on the pipe-to-ground resistance of the feeders. This resistance in turn depends on:

- *Method of grounding* the pipe-type feeder in the substation (resistor, PC, or ISP). Station ground mats can themselves pick up stray currents. If the resistor bar is still in place, these strays flow through the bar onto the pipe and cause the pipe to corrode at the point of discharge. Replacing the resistor with PC or ISPs virtually eliminates stray current pickup through station ground mats.

- *Accidental contacts* with other buried metallic structures. Periodic electrical surveys of these feeders are conducted to find the locations of any accidental metallic contacts between the feeder pipe and other buried metallic structures. These areas are excavated and the contacts cleared.
- *The coating quality* on the feeder pipe. Even if all stray pickup is eliminated through station ground mats, and by the elimination of accidental contacts, some strays will be picked up through the coating because its resistance cannot be infinite. In the case of two parallel forced-cooled feeders installed in one trench, two 25.4 cm (10 in.) pipes and two 12.7 cm (5 in.) pipes acting as one conductor for the purpose of calculating stray currents, a relatively high coating resistance of $200,000 \Omega \cdot \text{ft}^2$ would result in a pipe to

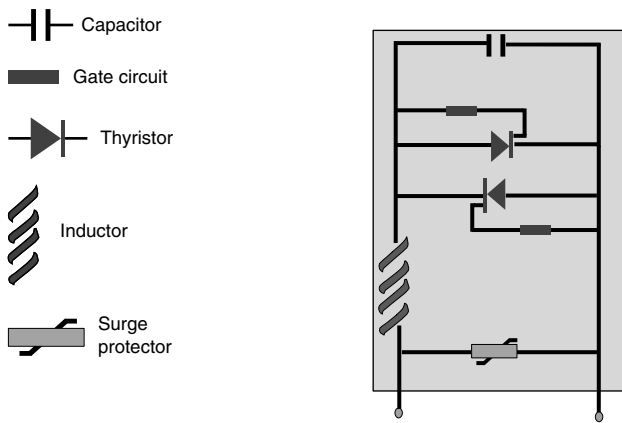

Fig. 4 Isolator surge protector components. The various components work together to keep the pipe-type cable effectively grounded during ac faults.

Fig. 5 Field rectifier and groundbed. Rectifiers are removed from their substation locations and are replaced by fewer, smaller rectifiers in the “field.” The current required by the pipe (I_R) is impressed by the rectifier via anode-groundbeds. One rectifier as shown could theoretically protect the pipe, but in order to lower the current impressed by each rectifier, smaller rectifiers at multiple locations are preferred. The single underground pipe-type transmission cable with a mild steel outer wall branches into three separate pipes at the substation termination. These are generally stainless steel.

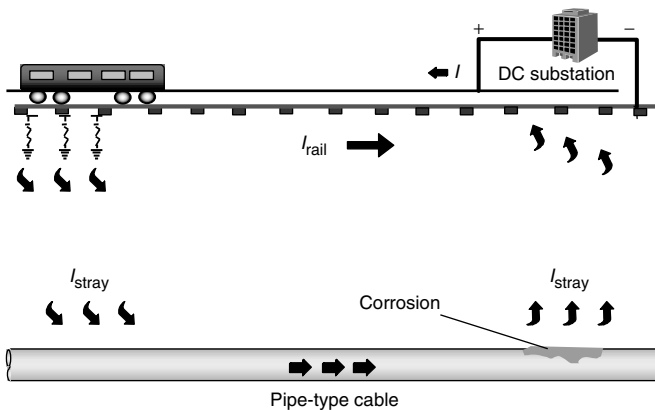

Fig. 6 Stray current interference. Most of the current that powers dc trains returns to the substation via the rails. A small portion of this current “strays” from the rails and is discharged into the ground. The pipe-type cable provides a low resistance return path. Localized corrosion can occur where the stray current is discharged by the pipe-type cable as it flows back to the train’s dc substation.

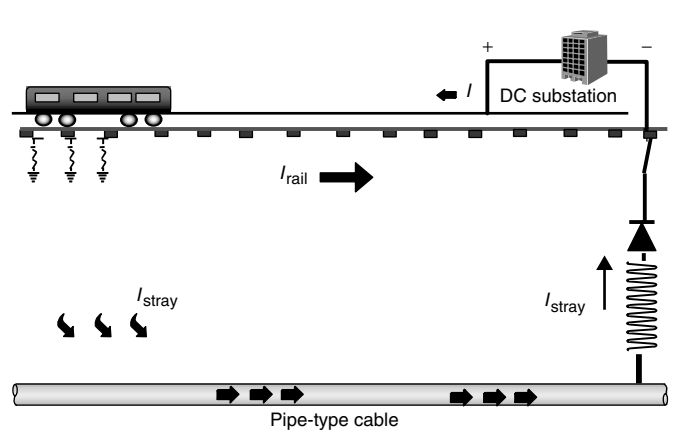

Fig. 7 Stray current drain bonds. Drain bonds prevent stray current picked up by the pipe-type cables from being discharged back into the ground. The drain bonds provide a metallic return path to the substation. The diode in the circuit prevents reverse currents.

ground resistance of approximately 5 Ω per mile. Since the stray current pickup areas can extend for several miles and since old dc rail systems often impress large voltage gradients in the soil, it is possible to pick up considerable amounts of stray current through the coating. In this example, pipes are 25.4 and 12.7 cm (10 and 5 in.), coating resistance is 186,000 $\Omega \cdot \text{m}^2$, and the resulting pipe to ground resistance is 3.1 Ω/km .

The strays that are picked up travel along the pipe until, due to the change in the polarity of the earth gradients, they are discharged back into the earth resulting in corrosion failures. Stray current discharge areas are generally more localized than pickup areas and occur in the vicinity of dc power stations or other grounded structures. These include bridges, tunnels, overpasses, and support structures for elevated lines. In each case, testing must be done over the route of the feeder to determine the extent of the exposure areas and appropriate action taken.

These remedial actions include the installation of:

- *Impressed current rectifier* systems to overcome the adverse effects of strays. Although these rectifiers can be effective in resolving these problems, they have one major disadvantage: they must be designed to correct the highest level of interference that occurs over a 24 h period. For transit systems these peak levels occur for only a small portion of the day, so the rest of the time the excess rectifier output is being wasted and more importantly can itself cause interference on other structure. Potential-controlled rectifiers have not proven effective in responding to the variations in potentials associated with dynamic stray currents.
- *Stray current drain bonds* to return stray currents to their source (Fig. 7). These bonds are the most effective way of mitigating the adverse effects of stray currents because, unlike rectifiers, they operate only when they

need to. Their operation is completely dependent on the level of stray current activity so that during rush-hour periods they may operate at full capacity, but are essentially inactive during non-rush hours and evening or night hours. Their effectiveness also depends on their proper design and location. It is important that the affected transmission cable operator works closely with the local transit authority personnel, both directly and through local coordinating committees to choose the appropriate location for stray current drain bonds. In addition, the bonds must be designed with appropriate resistors so that the interference can be mitigated with minimal current flow and with diodes to ensure that the current flow is unidirectional, from the pipe to the transit authority substation.

More information on this general subject is contained in the article "Cathodic Protection" in *ASM Handbook* Volume 13A, 2003.

Corrosion in the Military

Vinod S. Agarwala, Naval Air Systems Command, U.S. Navy

CORROSION IN THE UNITED STATES MILITARY is a matter of serious concern; it is estimated to cost at least \$20 billion per year, and the cost is rising. The U.S. Department of Defense (DoD) has been combating this for years and has now taken a proactive role to minimize these costs. Worldwide, the total annual cost of corrosion is estimated at over \$1.9 trillion for 2004 or roughly 3.8% of the world gross domestic product (GDP). This is a heavy tax burden on any country's economy, whether small or large. Currently, the U.S. DoD is facing the cause and effects of corrosion in its budgetary plans where maintenance and repairs of weapon systems, support systems, and military infrastructures have taken a high priority over new acquisitions (Ref 1). In addition, national priorities under present worldwide conflicts have imposed new requirements whereby the aging fleet of weapons systems has to continue to perform in service even longer than their intended service lives.

The articles that follow in this Section of the Handbook provide an overview of the problems, concerns, and solutions the defense agencies and their contractors are dealing with on a routine basis. Attempts have been made to include the following relevant subject matters: military specifications and standards; corrosion of military facilities; ground vehicle corrosion; armament corrosion; design, in-process, and field corrosion problems; high-temperature corrosion/oxidation; military aircraft; engines and turbine blades in naval environments; protective coatings in military applications; corrosion fatigue in military aviation; corrosion of electronic and electrical systems; micro-biologically influenced corrosion; and service life and aging of military equipment. These topics are intended to provide a brief account of the types and magnitude of corrosion problems the military attempts to mitigate. They also seek a reasonable way to estimate the corrosion damage and costs to provide a basis to develop policy for new acquisitions and new design and engineering specifications. In particular, this article provides a brief overview of some of these aspects and major issues and actions the U.S. military takes in corrosion control and mitigation.

Introduction

The effects of corrosion across all three services in the United States (Army, Navy, and Air Force) are immense (Ref 1, 2). The U.S. DoD owns a vast array of physical assets, ranging from ground vehicles, aircraft, ships, ammunition, and other support systems to infrastructures such as wharves, buildings, utilities, and many other stationary structures. Hence, there is a major budgetary concern in routine maintenance and operations (Ref 1–8). Also, as military systems are pressed into increasingly longer periods of service in various theaters of operation, limitations on the performance of the equipment and materials selected a few years ago are becoming increasingly evident. They mostly manifest themselves in terms of greater maintenance, repairs, spare parts, and other types of rework that hinder new acquisitions (Ref 2, 7–9).

Historically the effects of corrosion were ignored and considered inconsequential because, whenever problems occurred, maintenance was done by replacement of parts and without any care for how many hours it took to do it. In times of military conflict, the maintenance and repair practices adopted more often than necessary were to make sure that fleet readiness requirements were complied with, and the DoD appropriated the funds necessary for such practices (Ref 2). In the worst-case scenarios, adequate budget was provided to retire nonoperative, unsafe, and/or unreliable equipment without considerations of their life expectancy, and new systems were acquired in their place (Ref 7, 8).

Immense resources are usually needed to find the problems and then fix them to a level of reliability, safety, and predictability during military operations. These mandated actions contribute significantly to the total ownership cost of military systems, thus, leaving very few dollars for innovation and advanced material development. When these recurring costs became overwhelming, the U.S. General Accounting Office (GAO) mandated that the DoD take action to reduce corrosion costs (Ref 1). The DoD is now (2006) establishing the strategic policy that implements best-known corrosion engineering principles and practices in

basic systems design and material and processes selection, based on a fundamental acceptance of the fact that defense materials operate in one of the most corrosion-susceptible environments (Ref 9).

DoD Directives on Corrosion. Under the direction of the U.S. Congress, the GAO examined the impact and the extent of corrosion problems within the DoD. The GAO investigations considered the \$20 billion annual corrosion cost unacceptable and recommended that the DoD take action and adopt proper corrosion prevention and control practices in all weapons systems, support systems, and military infrastructures. The Congress also enacted law [Title 10 U.S.C. 2228] with a directive to DoD management to focus its effort on reducing life-cycle costs of their weapon systems, facilities, and infrastructures. The Congress also directed the GAO to monitor the DoD's progress on the development and implementation of overall corrosion prevention and control strategy. Thus, the Office of Corrosion Policy and Oversight was created by the Under Secretary of Defense for Acquisition, Technology, and Logistics, whose objectives are to institute policies that reduce costs and review "who is doing what" to reduce corrosion. However, the directives mentioned little or nothing about how to go about actually reducing corrosion in military systems. Recently, the Office of Corrosion Policy and Oversight issued two publications: "Corrosion Prevention and Control Planning Guidebook," Spiral No. 1 and No. 2. These publications provide program managers and design engineers the guidance on how to actually select materials in the design process that will institute corrosion prevention and control and enhance weapons system service life. It would be useful for the DoD to mandate corrosion control designs and engineering practices to enhance operational capabilities, sustainability, readiness, and safety in the design phase of weapons systems.

Almost all materials used in weapon systems are predictably susceptible to corrosion, stress-corrosion cracking (SCC), and corrosion fatigue (CF) (Ref 10, 11). They include predominantly aluminum, magnesium, and titanium alloys, steels, and graphite-reinforced composites. Stress-corrosion cracking and CF are

corrosion-related premature failure phenomena that occur in high-strength structural components under internal and/or external stresses. Cracking due to CF occurs only under cyclic or fluctuating operating loads or stresses, while failure from static or slowly rising loads result in SCC and hydrogen embrittlement (HE) or environmentally induced cracking. The latter usually occurs with certain high-strength alloy systems such as steels and titanium alloys sensitive to hydrogen.

In addition, most defense weapon systems have numerous structural joints such as butt, overlaps, fastener, weld, and dissimilar metal joints, which make corrosion prevention and control an essential strategy to prevent crevice, pitting, and galvanic corrosion. The technologies that isolate joints from electrolytic conduction, coating systems that serve as corrosion-resistant barriers or sacrificial coatings, corrosion preventive compounds (CPCs) as temporary environmental masks, and alloys that are less susceptible to corrosion, SCC, CF and HE are required (Ref 11). In order to minimize maintenance costs, condition-based maintenance (CBM) using devices that can detect and monitor corrosion "structural health" as find-and-fix tools are implemented when it makes economic sense (Ref 12).

This article reviews corrosion problems in the DoD and discusses management and maintenance aspects of the present (2006) and past practices that address cost and readiness. It also describes future plans to institute corrosion prevention and control strategies under new DoD directives in engineering design, material selection, and fabrication processes for new acquisitions.

Military Problems

Corrosion is very indiscriminate and affects all military assets including 350,000 ground and tactical vehicles, 15,000 aircraft, 1,000 strategic missiles, 300 ships, and approximately \$435 billion worth of facilities (Ref 2, 13). The cost of corrosion in the military is enormous (Ref 13). Although it is difficult to capture the indirect costs such as equipment downtime and reduced readiness and deployment capacity due to corrosion damage, the direct annual cost is between \$10 and \$20 billion. Corrosion initiated by land, air, or sea operational environments may have different magnitudes of problems, but in due course they become equally devastating in cause and effect with an immense drain on the economy. Although corrosion of warfighting machines is well acknowledged and even documented, what is not acknowledged are the ravages of corrosion on military-base facilities, shore and inland constructions, infrastructures such as gas, oil, steam and water pipelines, piers, docks and docking platforms at ports, hangers and runways, electrical and power lines and equipment, reinforced concrete structures, storage tanks, housing units, and so forth.

The Electrochemical Concept

Corrosion problems in the military environment are not different than those experienced in the civilian sector. The nature and perhaps the magnitude of corrosion, except when military equipment is deployed in combat during conflict, are almost the same. However, in order to appreciate where and why corrosion occurs, some understanding of corrosion fundamentals is necessary. The thermodynamics or free-energy states of materials used in the construction of equipment for both military and nonmilitary applications are always in the negative domain. Figure 1 illustrates "the corrosion cycle" in which all metallic materials exist, eventually returning to their lowest energy states of oxides/ores from which they were originally produced or extracted. All forms of corrosion are undesirable; however, those that are localized or preferential in nature, such as pitting, crevice, intergranular, and galvanic corrosion are the most insidious destroyers of the physical and mechanical properties of a material (Ref 14). Such forms of corrosion may lead to stress cracking, fatigue, fretting, cavitation and hydrogen-assisted damage, or embrittlement cracking, if not managed properly.

Pitting and crevice corrosion are the most frequently observed forms of corrosion in almost all weapon systems. In dynamic structural components they cause the most damage. Pitting is an autocatalytic process and often leads to serious cause-and-effect situations where fatigue is involved; it is particularly damaging to critical aircraft structures such as landing and arresting gears, hinges, and load-bearing struts. Figure 2 shows the reactions and mechanisms of how a material corrodes and forms a pit. The pit grows in a corrosive environment of acid and chloride by an autocatalytic action (shown in reactions 4 and 5), whereby new material corrodes to form chloride, which then hydrolyzes to form HCl and the cycle keeps repeating. This makes the pit grow deeper. In addition to metal dissolution, as shown in reactions 1 and 5, there is another (cathodic) reaction which occurs that involves consumption of electrons produced. This ca-

Fig. 1 The corrosion cycle illustrating the need for energy to convert oxides/ores to metallic form. If not protected in-service, the metal reverts back to oxides due to corrosion.

thodic reaction produces hydrogen, first in the atomic state and then in the molecular state. In the atomic state, H is adsorbed and then absorbed at the apex of stress under mechanical load and lowers the ductility of the region by a process called embrittlement, creating a plastic zone. When the modulus of this plastic zone is exceeded by mechanical working (such as fatigue), a crack initiates and grows rapidly. In high-strength structural components, such as landing gear, this phenomenon may lead to catastrophic failure. The montage in Fig. 2 illustrates where oxides or corrosion products collect due to dissolution of metal in the pit and where hydrogen evolution and absorption occur causing HE and cracking.

Pit-Initiated Cracking. The cracking model, as shown in Fig. 2, illustrates the mechanism of pit formation and growth through corrosion action of chloride and acid by an autocatalytic process. Figure 3 shows the schematic of crack initiation and growth from the pit under cyclic mechanical loading. Under tensile loading (fatigue half cycle) the pit, as shown in Fig. 3(a), leads to the generation of a new surface in its bottom by slip deformation and produces a step D, shown in Fig. 3(b). This step D is very reactive and dissolves very fast, as shown in Fig. 3(c), and flattens out or creates a trough which under compression (second half cycle) pushes back the step to create a crack as illustrated in Fig. 3(d). This process repeats with every cycle and the conjoint actions of corrosion and fatigue lead to a much greater increase in crack growth rates than one would expect under pure fatigue mode. The illustration of such a pit-initiated service failure is shown Fig. 4. The collapse of the main landing gear of an F/A-18 aircraft strut (a load-bearing cylindrical support) of high-strength 300M alloy steel (UNS K44220) under its own weight was due to severe pitting and crevice corrosion found all around the barrel, and high-pulse load fatigue was a serious warning of the shortcomings in the inspection protocol and techniques (Ref 10).

Galvanic Corrosion. In addition to CF and SCC, galvanic corrosion of dissimilar metal joints such as in electrical and electronic boxes, and in structural assemblies caused by exposure

Fig. 2 A cracking model illustrating the mechanism of pit initiation and growth and hydrogen embrittlement (HE)

to wet environment, is the most widespread form of corrosion in almost all weapons systems. Although this problem can be easily solved by separation of the joints with a nonconductive sealant, gasket, or coating system, it continues to cause serious concerns in maintenance and repair. It is almost impossible to avoid dissimilar joints in which one metal is electrochemically more active than the other. The best practice is to choose materials that are as close to each other as possible according to the galvanic series. The objective is to avoid large potential drops, which are the driving force for corrosion to occur between the two metals (see Table 1).

Of course, materials selection for a component is often dictated by the engineering requirements of the physical and mechanical properties and rarely if ever by their electrochemical compatibility (Ref 15–17). However, one can always separate the anodes from the cathodes by using electrical insulators such as sealants and barrier coatings. For underwater systems, such as ships and submarines, in addition to coatings, cathodic protection is commonly used in the Navy. When designing a fastener system, unfavorable area ratios must always be avoided when using dissimilar metal combinations. Active alloys must

not be used as small-area components in large surface area cathode materials, such as aluminum bolts, fasteners, and hinges in steel or titanium. Small area anodes would corrode much faster and preferentially, thus compromising the joint.

Aging Systems

Corrosion of military equipment and facilities is an ongoing problem that exacerbates with time and becomes more significant in yearly costs to protect the assets, affecting new procurement and maintenance. The DoD has a large aging fleet of aircraft, ships, land and amphibious combat vehicles, ammunitions, and submarines that require tremendous repair, modification, and upgrade costs to extend their life to perform into the 21st century. For both the Air Force and Navy, aircraft are high-cost items with almost 30% of the fleet more than 25 years old (Ref 8, 10, 11). Since corrosion is a time-dependent phenomenon, the goal of corrosion-control schemes is to slow down the rate of corrosion. The slower the corrosion kinetics the longer the service life. On airborne systems, limitations on the choice of materials and design engineering

impose a design life of approximately 20 years. This of course changes and mostly depends on theater of operation, loads and stresses, the combat environment, and the time spent at sea. For naval aircraft, the aircraft carriers are their platforms and base of operation for approximately 90% of their life.

The average age of major battle force ships (carriers, destroyers, cruisers, amphibious ships, and submarines) was 14.5 years in 2000 compared with 13.6 years in 1980 (Ref 8). Today (2006) most ships continue to perform in service at a cost of approximately \$1500/per steaming hour, a cost that has not changed much during the last 20 years, except during the early 1990s where reduction in the size of the fleet allowed the service to retire many older ships. Ship systems corrosion is controlled with generous use of coatings and periodic maintenance. The cost of maintenance of ship systems was nearly \$15 million per ship in 1984. With the retirement of older ships, the cost has been reduced to \$9 million per ship.

Land-based vehicles for the Army, which number in tens of thousands, although not as old as the fleet, suffer from extensive corrosion because of lack of concern for corrosion or its effect on vehicle performance (Ref 8). Consequentially, there have been poor choices made regarding selection of materials, engineering designs, combination of materials in joints, and use of inadequate coating systems to protect them from corrosion effects. In particular, most vehicles, such as light armored vehicles, Bradley and Abraham fighting vehicles systems, and high-mobility multipurpose wheeled vehicles (HMMWV) suffered seriously from galvanic and crevice type corrosion. As a result, their life expectancy was reduced from 10 to 3 years. It may have been called an “aging problem,” but it is more an engineering design and corrosion-control problem. Construction materials in these vehicles are usually carbon steels and, if not protected, will corrode irrespective of the implied life or age. Aging of military facilities is another high-cost item and is discussed in the section “Facilities Problems” in this article.

Navy Problems

The U.S. Navy operates its oceangoing, airborne, and shorebound assets in one of the most corrosive environments known on earth, seawater, combined with marine species, airborne pollutants such as sulfur dioxide (SO_2), nitrogen dioxide (NO_2), and carbonaceous matter as exhaust produced from burning of fuel by ships and aircraft. Salt fog and salt spray seriously degrade the readiness of ships, aircraft, landing craft, shore/harbor facilities, and even land vehicles in oceanic transit. According to a 1993 estimate, the total direct cost of corrosion for all naval systems is \$2 billion per year (Ref 2, 8). Corrosion prevention and control at all levels is one of the primary directives of the Naval Sea Systems Command (NAVSEA) and the Naval Air Systems Command (NAVAIR). The Office of Naval Research (ONR) directs programs toward development of new technology to reduce total ownership costs.

For ship systems, the largest and highest priority is in the protection of ship hulls (interior and exterior), decks (topside and well-deck), tanks (ballast and wastewater), and voids (cavities in hull walls) that are primarily steel structures (Ref 18). For NAVSEA, the primary defense against corrosion is the meticulous use of protective coatings everywhere; on underwater hull structures, cathodic protection schemes are also used. The types of coating systems used on a Navy ship vary with location and are shown in Fig. 5. Coatings are the biggest maintenance driver for ship systems as they cover nearly 7.1 million square feet of surface that include flight, freeboard, topside, and well-deck areas (Fig. 6) (Ref 19) and costs the U.S. Navy approximately \$975 million a year (Ref 2). These coatings traditionally last less than 10 years, at which point the ship goes to dry dock to remove and apply new coatings. The maintenance-related dry-dock labor costs due to corrosion are about \$4 million per year per ship in the fleet (Ref 4).

Most maintenance actions are done in tanks and voids that hold seawater as ballast, fuel, storage, potable water, sewage waste, sludge, and lubricating oils. The life of the epoxy coat-

ings used in these areas is usually short, less than 3 years. The new advanced high-solid epoxy coating has increased the life to almost 10 years. Figure 7 demonstrates the performance of this new high-solid epoxy coating system where it has been used on a shipboard tank of the U.S.S. Ogden (Ref 18, 19).

The impact of corrosion on the life-cycle cost of military aircraft systems is very significant, nearly \$3 billion per year (Ref 2, 19–25). For naval aircraft alone it is estimated as nearly \$1 billion per year (Ref 2, 19–20). Since NAVAIR has varieties of aircraft in its inventory such as surveillance, strike, rotary wing, trainers, tankers, and transport, the corrosion problems also vary greatly and depend upon their mission and area of deployment. It must be noted that corrosion problems of Navy aircraft are exacerbated by several environmental and stress factors and sometimes work conjointly to cause catastrophic damage. Naval aircraft operate in the most severe corrosive environments. The service conditions include:

- Being stationed at sea for long periods of time on aircraft carrier flight decks

- Facing the challenging environments that contain chloride, sulfate, SO_2 , and other marine seawater species (Fig. 8)
- Being subjected to high electromagnetic fields or electromagnetic interference (EMI) environment
- Being exposed to solar radiation effects
- Being serviced in a very limited space to perform adequate maintenance for corrosion protection

The impact of time (aging) on sustainment and readiness of aircraft is the next greatest challenge facing naval aviation. Here the issues are that almost 50% of the naval aircraft are more than 20 years old and require increasing maintenance to keep them in service. The biggest concern today is that these aircraft have been slated to continue in service for another 20 years (Ref 20). This has imposed a tremendous pressure on operational safety, readiness, and the maintenance budget. The added expense will take away the thrust from innovation that comes from research and development programs.

If one tries to identify the single most important issue on aging aircraft, it is structural

Fig. 6 Examples of coatings on surface ships. Topside (right side), freeboard (lower left), and well-deck (upper left) areas require very frequent stripping and repainting.

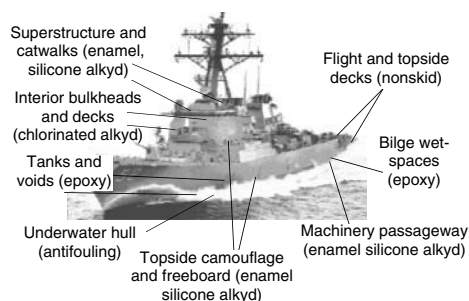

Fig. 5 Shipboard coatings are a major maintenance driver for corrosion control. Navy ships use a variety of organic coatings for interior and exterior applications.

integrity where effects of corrosive environment make a serious impact on fatigue life of critical load-bearing structures and components of aircraft (Ref 13). Thus, the Navy is seriously looking into development and design of sensors that can be used to provide diagnostic and prognostic aircraft health management tools as discussed in Ref 15 and 19 and the article "In-Service Techniques—Damage Detection and Monitoring" in Volume 13A of the ASM Handbook (Ref 21). Under joint services, the structural prognostics and health management (SPHM) corrosion and strain monitoring program is expected to provide a predictive modeling tool that offers more accurate assessment of their expended service life and facilitates condition-based maintenance (Ref 22). Such schemes are in place now for the new Joint Strike Fighter.

Among 14 aircraft systems evaluated by NAVAIR, the major cost drivers by aircraft fall in the following order: surveillance (structures and avionics), strike (structures, subsystems, and landing gear tailhook), and rotary wing (dynamic components, pumps, landing gear, hydraulics). Major depot-level repairs were related to corrosion and aging (50%), obsolescence (14%), and design and item change (25%) (Ref 23). The order in which most repairs are done are: avionics, dynamic components, electrical/power systems, structures, subsystems, and engines (Ref 23). The Navy has three levels of maintenance for their aircraft: (1) organizational maintenance is performed on individual equipment at squadrons and include inspection, servicing, small parts replacements, and some assemblies; (2) intermediate maintenance is conducted on parts removed from the aircraft and includes calibration, repair, and replacement of damaged components at operational sites or wings; and (3) depot-level maintenance is conducted as an overhaul or major refurbishment and rebuilding of parts, subassemblies, and end items, including manufacture of parts, modifications, testing, and recycle. This is done at one of the three depots within the continental United States.

For naval aircraft, coatings are the first line of defense against corrosive aircraft carrier environments. That is why the Navy aircraft coating system has to be highly resistant to the operational environmental. The coating generally comprises pretreatments, such as a chemical conversion coating that serves as corrosion inhibitor and prepares the surface for bonding with paints. This pretreated surface is sprayed with epoxy polyimides containing corrosion-inhibitor additives and then with a topcoat of polyurethane containing filler materials for protection against ultraviolet (UV) and other radiations. Since coatings do wear or break down, repainting is one of the major repairs done at the organizational level, that is, at squadrons. Squadron repairs are limited to touch-up painting (Ref 19). Squadrons have also been supplied with CPCs for more generous use as a spray treatment on top of coatings to prolong service life.

The use of sealant on all joints and around fasteners is mandatory for all Navy aircraft. Sealants are adhesives and corrosion-inhibiting compounds formulated in the form of a paste, rope, or tape and are typically applied at lap and stringer-to-skin joints and around fastener holes. Their primary function is to eliminate crevice corrosion and isolate dissimilar metal joints to avoid galvanic corrosion (Fig. 9). In particular, steel and titanium fasteners on the exterior of the aircraft must always be installed with sealant. All internal structural crevices, cavities, and corners are suspect locations for moisture collection and hence must be protected by using a flexible sealant and then a coating. In most applications, polysulfide or room-temperature vulcanizing (RTV) elastomeric sealant, polythioether, and fluorinated resins such as Skyflex (W.L. Gore & Associates, Inc.) are commonly used. Polysulfide sealants, which have short life before they harden with time and under UV exposure, are problematic in providing crevice corrosion

resistance and replacement repairs. The other two varieties stay more flexible. In applications where electrical joints or antenna mounts are involved, gasket-type seals are best suited. The commercially available gaskets like HiTak (Logis-Tech, Inc.) and Av-Dec (Aviation Devices and Electronic Components, LLC) have found much use in such applications. Often, preshaped gaskets of sealant materials are more economical than handheld sealant itself.

Air Force Problems

The major corrosion issues with the Air Force is related to aging of aircraft (Ref 24, 25). Although the Air Force did not ignore the corrosion problem for the past few decades, it had followed a "find and fix it" mentality. It did have programs in place to detect, quantify, mitigate, and address generalized, structural, and cosmetic corrosion for many years in their aircraft

Fig. 8 Naval aircraft carrier flight deck environment containing salt fog, hydrocarbons, and engine exhaust gases such as SO_2 , NO_x , and so forth

Fig. 9 Severe crevice corrosion of aluminum plate under the antenna mounts resulting from the absence of sealant in the joints

systems. Now (2006), the Air Force has a well-developed program called Aircraft Structural Integrity Program (ASIP) to monitor and control fatigue cracking.

Transport and tanker aircraft such as C-130, C-141, and KC-135 have experienced and continue to experience severe internal/hidden corrosion damage and problems of SCC in their primary structures. Legacy aircraft, such as the Navy P-3C, suffer with similar problems (Ref 26). The Air Force aircraft problems largely emanate from very little use of sealant in the joints and around fasteners and from accepting the impact of corrosion. This perspective originates primarily from the belief that land-based aircraft, as compared to those of the Navy, are not subjected to corrosion. Of course, even land-based environments are corrosive (humidity, industrial pollutants, acid rain, etc.), and corrosion damage will accumulate with time. Most Air Force aircraft corrode from inside out as they are not properly inspected for hidden corrosion (Fig. 10) (Ref 12, 24). This penalizes Air Force aircraft significantly in cost, readiness, and survivability (Ref 1, 2). An estimate shows that the Air Force spends nearly \$900 million per year in direct corrosion maintenance costs (Ref 1, 12).

The present Air Force maintenance strategy includes comprehensive inspection for corrosion, fatigue, and stress cracking, repair of all corrosion damage, periodic washing and rinsing of aircraft, application of sealant in most joints, and use of preshaped gaskets in most electrical boxes, antenna mounts, and connectors to avoid environmental intrusions (Fig. 9). The Air Force has authorized the use of film tape type sealant to apply on spars, ribs, and decking structures.

To address the problems of SCC and CF in primary structures, airframes, and skins, alloy substitution to replace corrosion-prone materials such as aluminum alloy 7075-T6 has been established by the Air Force. A user-friendly software was developed to make use of MIL-HDBK-5 data (now MMPDS) for drop-in replacements of certain alloys. For example, alloys 7055-T76 and 7055-T74 are excellent replacement candidates with much better exfoliation resistance (ASTM Standard G 34, rating EB), and almost double the threshold for SCC (Fig. 11) (Ref 12, 24).

Fig. 10 Corrosion of the aircraft structure from the inside. A hidden corrosion phenomenon called "pillowing" occurs where corrosion products grow under the aluminum skin and puffs up the top surface of the thin metal sheet in the area around fasteners.

Army Problems

Corrosion problems in the Army are widespread (Ref 1, 2). Global conflict necessitates transport of warfighting machines and support equipment via ocean routes that expose them to the moisture and salinity of the marine environment (Ref 27–30). Ocean transits take up to 14 days on average, but equipment is often stored at the port of embarkation (port staging area) for several weeks or months waiting for a ship. Once shipped, it is off-loaded at the port of debarkation, awaiting cleanup and shipment to its assigned unit. This often takes months, and during this time equipment is subjected to continuous wetting and drying cycles of the salt spray from the shipboard environment. This creates damage to inner cavities of components that mostly go undetected and unremoved (Ref 30). In spite of the fact that all military equipment is protected and pretreated with corrosion prevention technologies before shipping, the removal of corrosion-causing elements deposited during oceanic transit becomes necessary (see Fig. 12). Although washing and rinsing is part of the scheduled maintenance policy, the availability of clear (fresh) water at destinations becomes a serious problem. The Army has a portable wash facility called "Bird Bath" that they install at deployment sites for rinsing and washing of all tactical ground vehicles and helicopters. Although rinse facilities are expensive to install and cost about \$2.2 million each, they do have tremendous potential for controlling corrosion damage and more importantly on readiness (Ref 30).

The Army has nearly 340,000 units of tactical ground vehicles and ground-support equipment, and 2,770 helicopters and fixed-wing aircraft that require constant corrosion protection. It spends nearly \$6.5 billion per year in corrosion repairs. Their major corrosion cost items are helicopters, HMMWVs, and howitzers (Ref 2, 27, 28). The Army helicopter corrosion repairs are very extensive and are performed on skin, structural frames, engine, transmission beams, rotor blades, and controls. This alone costs nearly \$4 billion per year. It is primarily due to lack of or very little corrosion protection on most surfaces. The use of sealant material in laps, joints, and

around fasteners, and the presence of inhibitors in rinse wash was not practiced much in the past. In 2000, the Army reported that 40% of their helicopter fleet was not combat-ready.

Corrosion is a major concern for all tactical ground vehicles, including Bradley fighting vehicle systems, Abraham tank systems, and HMMWVs. Among them, the HMMWVs were the most corrosion-prone vehicles (Ref 1, 2, 27). These are essentially light trucks designed to operate in an all-terrain environment. Poor corrosion prevention designs and inadequate material selection and corrosion repair requirements put them out of service in less than 12 months. The most commonly identified shortcomings in these vehicles are: the use of nongalvanized 1010 carbon steel with no protective coating, thousands of unprotected rivets forming galvanic couples, inadequate paint system, and no protection against chemical agents that could rapidly destroy coating systems. These vehicles cost the Army-nearly \$2 billion dollars per year in corrosion repairs and maintenance costs. The Marine Corps also uses these Army-procured vehicles and has had to face even worse consequences as they are operated in an even more corrosive environment.

The other significant corrosion cost contributors in the Army are the towed howitzer firing platforms. These 2300 firing cannon platforms suffered severe corrosion in unprotected dissimilar joints and areas on the platforms where water could collect. Their designs were so poor that the water-drain holes were not located at the lowest gravity point. The replacement cost for these platforms is \$18,000 each with new designs (Ref 2).

Facilities Problems

There is a lack of awareness of corrosion problems associated with facilities at various military bases. The DoD has approximately 200 air bases, 40 naval ports and air stations, and numerous (in several hundred) Army and Marine

Fig. 11 Exfoliation corrosion resistance of alloy 7055-T765 (ASTM rating EB) is much superior to that for 7075-T65 (ASTM rating ED)

Fig. 12 Army shipment (equipment) via sea is exposed to the elements of marine environment during transportation

Corps facilities, which are located throughout the world (Ref 2). These extensive facilities consist of land and port infrastructures such as hangers, airfields, docks, waterfront piers, fuel storage tanks, barracks, housing, heat exchangers, electric and gas supplies, drinking water and sewer systems, bridges, and miles of railroads, pipelines, and concrete runways. These facilities experience corrosion issues that are similar to those in the civilian sector. One of the major high-cost issues is degradation of concrete, which costs in billions of dollars annually (Ref 1, 2, 31). Cracking of concrete airfields for all of the military poses severe safety hazards, impairs readiness, and increases maintenance costs.

One cause of this deterioration is the corrosive action of water with concrete (Ref 1, 31) or, more specifically, with alkali in the concrete that causes concrete to crack by expansion as shown in Fig. 13. This action is called alkali-silica reactivity (ASR), and it decomposes concrete through the thickness (bulk of pavement). The Navy has found ways to mitigate concrete corrosion problems by counteracting the effect of ASR through advanced formulation and improvement of cement. A Navy study proposes using 30% fly ash as a partial replacement of portland cement. It would allow immediate reduction in the material cost of concrete by half and double the concrete life (Ref 22). This alone is estimated to save the Navy \$9.5 million per year (Ref 32). The deterioration of Channel Islands Air National Guard airfield is an example of concrete degradation due to moisture and salt (Fig. 13). It was built in 1978 and then repaired in the 1990s at a cost of \$14 million as a result of ASR. This airfield showed extensive surface (apron) damage and cracking and concrete decomposition through the pavement thickness.

Corrosion of steel reinforcement is the most common form of deterioration in marine concrete structures (Ref 32, 33). The cost to repair damages of a single pier is often in the millions. An example of rebar corrosion and degradation of concrete of piers on a bridge in Hawaii is shown in Fig. 14. The recommended practice is to use epoxy-coated rebar in pier construction, which delays onset of rebar corrosion. With the help of ASTM Standard A 934 (epoxy-coated rebar), Navy Facilities Command has developed a user guidebook that provides specifications on epoxy-coated rebar technologies for all rebar-cement construction. In new constructions and where economically possible, the use of stainless steel rebar and application of cathodic protection have been also recommended.

Corrosion Control and Management

Although a number of corrosion control initiatives have been mentioned, the following are reiterated and specifically described to show the significance of the maintenance actions. Most of the military services have either implemented

these initiatives or have plans to implement them in the near future.

Material Substitution. The most corrosion-prone aluminum alloys are 7075-T6 and 2024-T3. They are used in aircraft structures because of their high strength. Many newer, corrosion-resistant alloys, such as 7055-T7751, 7150-T77511, 2224-T3511, 2324-T39, and 2525-T3, developed in the past three decades, can now replace them (Ref 10–13). These newer alloys have high threshold to SCC, CF, and intergranular and pitting corrosion (Ref 12). Figure 15 shows examples of such alloys already in use on commercial jetliners such as the Boeing 777. In military applications, it is crucial that material substitutes in legacy transport, fuel carriers, and surveillance aircraft exactly match the mechanical properties of the materials they replace. Otherwise, it is possible to increase stress levels on abutting structures. Material substitutions have been recommended on the Air Force C-130 and C-5 and the Air National Guard C-141.

For the Navy's P-3C surveillance aircraft, several alloys with superior corrosion resistance

were investigated as possible drop-in material substitutes for parts that needed replacement due to extensive corrosion repair history. Among them, alloys 7150-T77511, 7249-T76511, and 7055-T7XXX emerged as prime replacement candidates. These alloys were fully characterized by the Sustainment Life Assessment Program (SLAP) by full-scale testing before any such substitution was recommended (Ref 26). With these substitutions, the aircraft are now expected to provide 30 more years of service life.

Retrogression Re-Aging (RRA). In some cases, where substitution is cost prohibitive, a newly developed heat treatment process called retrogression and re-aging (RRA) has been studied and perhaps would be recommended. This process was developed to keep the original strength of T-6 temper to within 90% of the yield strength, but most importantly increase the resistance of the alloy to exfoliation corrosion and SCC. The RRA treatment consists of a retrogression phase (heat to 195 °C, or 385 °F, for 40 min and oil quench) and then a re-aging phase (heat to 120 °C, or 250 °F, for 24 h and then air cool). The Air Force is currently investigating

Fig. 13 Concrete decomposition at Channel Islands Air National Guard airfield from alkali-silica reactivity. (a) The airfield, which was built in 1978. (b) Surface (apron) damage and cracking. (c) Concrete decomposition through pavement thickness. The cost of repair was \$14 million.

Fig. 14 Severe concrete degradation caused by rebar corrosion of piers of a NAVSTA bridge in Pearl Harbor, HI

this process using a special thermal blanket that can be placed on the actual aircraft skin of 7075-T6 alloy sheet metal and heated to approximately 200 °C (390 °F) for a short time and then rapidly cooled with a cold jacket and then re-aged by heating to 120 °C (250 °F) (Ref 34). The problem with such in situ application is that thermal conduction or heat sink by the structural frames attached to the skin is not quantifiable; hence, this treatment cannot be universally adopted over all the aircraft. The RRA parameters have to be determined for each location to get the optimum results.

Rinsing and Washing. The most effective procedure and closest to the immediate corrosion reduction initiative is washing and rinsing, in which a majority of aircraft and other weapon systems are washed and rinsed with waters containing corrosion inhibitors. The design of the facility depends on the types of aircraft, tanks, and ground vehicles. For helicopters the facility is like a “birdbath,” and for fixed wings and ground equipment it is the overhead spray type installed in the hanger or in the field. The Army, Air Force, and Navy all have such facilities at their respective maintenance facilities. Most wash and rinse facilities include a freshwater wash-injection system with corrosion inhibitors as additives. Generally, rinse facilities use a closed-loop system where water is recycled after a filtration and replenished with the additives for the next wash and rinse. The additives generally comprise a surfactant, cleanser, a pH modifier, and multifunctional inhibitors.

Some of these closed-loop facilities are deployable so that they can be installed on-site in

the regions of military conflict (Ref 30) where corrosion-causing species can be removed from the aircraft before they have time to initiate corrosion. This practice is also being used for tanks and ground vehicles, but not as frequently as for aircraft. In deployment conditions of extremely corrosive environments, washing and rinsing are most frequently recommended for all outdoor hardware systems.

Finding Corrosion and Corrosion-Assisted Damage. Recognizing the impact of corrosive operating environment on the integrity of military weapons systems, and the national economy, original equipment manufacturers and the DoD agencies have taken a significant interest in developing nondestructive inspection (NDI) and nondestructive evaluation (NDE) technologies. In the last three decades numerous innovative systems have been developed that play an important role in providing detection and monitoring of early signs of corrosive environments, corrosion, and corrosion-assisted damage. As the cost of corrosion damage continues to escalate in terms of maintenance man-hours, and lack of readiness, the demand on early detection devices to avoid major repairs and downtime is now increasing substantially. Condition-based maintenance has taken the place of scheduled or periodic maintenance. The following technologies are currently being used or introduced to address corrosion:

- Optically aided inspection—visual, bore-scope, fluorescence
- Thermal imaging
- Digital radiography

- Magneto-optic eddy current
- Guided wave ultrasonics
- Microwave scanning
- Electrochemical techniques—galvanic, resistance, and impedance type
- Eddy current—multifrequency, mobile automated ultrasonic scanner (MAUS)
- Neutron radiography
- Magnetic resonance spectroscopy
- Acoustic radio and thermal scanning
- Laser pulse-echo method
- Stress/strain sensing

The details of some of these techniques have been discussed in the *ASM Handbook* (see, for example Ref 14 and 21). Among these, the most recommended and preferred technologies are those that can be embedded or are the leave-in-place type and that can monitor the onset of corrosion and locate small cracks or pits as they occur (Ref 21). These early-warning devices detect corrosion damage before it becomes significant, minimize corrosion damage, allow small repairs that can be performed at organization or intermediate levels, and can extend depot-level maintenance by another few years (Ref 14). One of the devices called wireless intelligent corrosion sensor or ICS does just that. Through its thin-film galvanic sensor, it monitors the corrosive environment in hidden areas and active corrosion in joints and splices or under coatings. It is an autonomous stand-alone miniature device that measures, collects, stores, and then downloads the data at command through a handheld transponder or data-gathering device (Ref 25). This thin-film device can be attached in aircraft structural cavities or sandwiched in joints to detect the intrusion of corrosive environment.

Corrosion Removal and Repair. Once corrosion has been identified, removal of corrosion damage and the subsequent ability to make small repairs becomes an important initiative in the corrosion prevention and control program. This process requires the use of a kit that contains small repair tools, brushes, chemical tubes, and spray cans that can be applied at organization levels without having to wait until depot-level maintenance is scheduled. The kit is lightweight and contains only essential items for small repairs, such as a bristle disk for removal of corrosion products, touch-up pens, brushes and pads for surface pretreatment, conversion coating and primer, and topcoat. The kit allows in-field application to prevent spread of corrosion and extends the life of the structure. Programs are in place to extend this concept to repair materials other than aluminum. Whenever large surface areas are corroded, paint stripping becomes absolutely necessary. Under those conditions, immediately after paint stripping and removal of corrosion product, temporary corrosion protection schemes are needed before repainting and involve the use of CPCs.

Corrosion preventive compounds are dispersant liquids of solvent and sometimes water containing petroleum distillates, surfactants, and

Fig. 15 Material substitution on Boeing 777 aircraft. Aluminum alloys 7075-T6 and 2024-T3 have been replaced by 7055-T7 and 2324-T3 and other more corrosion- and SCC-resistant aluminum alloys.

corrosion inhibitors. There are several types of CPCs on the market, and all of them are used primarily for temporary corrosion protection in interior structures and cavities. They must be reapplied frequently or in some timely manner to be effective. Some CPCs are also applicable on the exterior surfaces. Appropriateness of a CPC product is based on their physical and chemical attributes, such as viscosity, dryness, lubrication, volatile organic content, smell, environmental compliance, surface wetness, hydrophobicity, corrosion protection period, and inhibition efficiency. The application of CPCs is widely accepted in hard-to-reach areas of all types of equipment, aircraft missiles, doors, hinges, bulkheads of ships, electrical boxes, galleys, wheel wells, joints, voids, finishes, and so forth. Since most CPCs wash away with water, reapplication is always needed and the preferred periods are 12 to 15 months. It is essential that CPCs used in moving components contain some lubricants and do not carry tacky or waxy substances that cause seizing and result in loss of mobility. In the selection of CPCs, one must practice caution and seek to match CPC property with the part design and its functional and material requirements. The following is a partial list of some CPCs that are commercially available: Dinitrol compounds (several grades AV-15, 30, 40, etc.); Cor-Ban 35 and Cor-Ban 22; CorrosionX; ACF-50; LPS 2, LPS-3, Procyon; SuperCorrB; Amalgard (a Navy developed product).

Protection and Preservation by Humidity Control. The presence of moisture is essential to corrosion. It has been well established that control of relative humidity (RH) controls the magnitude of corrosion (Ref 35–37). Numerous studies have shown that in components such as electrical and electronic boxes, and electrical wires and connectors, the effects of high humidity are significant. For example, the resistance of nylon insulation on an electrical wire can drop from 10^{14} to $10^7 \Omega$ if the RH is changed from 10% RH to 90% RH. All services have evaluated the benefits of controlling RH below 35% for their weapons systems and found it to be very effective in corrosion protection and preservation. Munitions and equipment stored in high humidity can experience severe corrosion and perhaps loss of functionality. Services have used temporary shelters such as makeshift hangers and clamshells and employed desiccant wheels to remove humidity from the interior of aircraft and missile systems and wheeled vehicles. Many foreign governments use humidity control as a maintenance technology for their weapon systems. The Europeans (The Netherlands, Belgium, Sweden, Italy, France, Germany, and United Kingdom) have been using this method to avoid corrosion since 1995 (Ref 35). Maintenance of low humidity, <35% RH, in weapon systems storage areas is essential to preservation and protection from corrosion. Low-humidity preservation also helps in readiness and quick deployment (Ref 37).

Corrosion Education and Training. Proper education and on-site training of technical personnel in the state-of-the-art corrosion science and engineering is necessary if a cost-effective corrosion control and maintenance program is to be implemented at DoD facilities. There are numerous sources for such training within the DoD such as the Tri-Service conferences, Army, Navy, and Air Force workshops, corrosion manuals and websites. In addition, schools such as Massachusetts Institute of Technology, University of Virginia, The Ohio State University, Case Western Reserve University, University of Southern California, University of Florida, University of Texas, Texas A&M and NACE International—the Corrosion Society—offer many corrosion courses such as corrosion basics, coating inspection, and cathodic protection. The DoD has also established a website that is available to approved members of the defense acquisition force. This website (www.dodcorrosionexchange.org, accessed Dec 2005) has an extensive database of military corrosion control products, specifications, guidebooks, and technology papers related to corrosion prevention and control.

Long-Term Strategy to Reduce Cost of Corrosion

The U.S. Congress has directed the DoD and its agencies to seek to mitigate the effects of corrosion and improve the department's coordination of corrosion prevention and control practices among the services. The long-term strategy includes:

- Consider life-cycle costs when new systems are procured
- Replace older equipment with new at a faster rate—accelerate modernization
- Reduce burden of maintaining underutilized infrastructure—close marginal facilities
- Establish a Corrosion Information Exchange Network, an Internet web-based tool for sharing best practices among the services, including construction of an *expert system*
- Revise/develop policy and regulations on design, acquisition, and maintenance of military equipment and make it specifically address corrosion prevention and mitigation
- Develop standardized methodologies for collecting and analyzing corrosion cost, readiness, and safety data. Increase use of industry standards for corrosion testing and evaluation of commercial products and processes
- Increase interaction with professional societies and private sector corrosion-focused organizations. Encourage NACE International to develop information-sharing network
- Continue to develop and test materials, processes, and treatments that reduce manpower, downtime, and costs associated with corrosion

- Develop a new or augmented strategy through survey of current corrosion control practices with metrics of cost reduction for each of the services. The purpose is to develop criteria for testing and use of best materials and processes from the collected consolidated database
- Mandate a requirement for corrosion education and training for all design engineers, maintenance personnel, and (even) program managers responsible for military hardware acquisition

An effort has been made to create a consortium of government, academia, and industry, which will address corrosion education as part of the existing DoD education forum and will be incorporated in its website. The intent of this consortium is to develop corrosion science and engineering education tools for the user community at large that contains lucid and comprehensive understanding of corrosion issues related to their sector interest including the impact of corrosion on the national productivity and the economy. A corrosion steering committee of experts from the DoD, academia, and industry has been established, and West Virginia University is spearheading the effort. NACE International has been selected as the major source for training and providing a database of technologies that could be available for general use.

Summary

Corrosion in the military has been traditionally treated as strictly a maintenance problem and has been argued as a “necessary evil.” Unfortunately this has gone on for too long and is costing the U.S. military nearly \$20 billion per year and jeopardizing the readiness of warfighters. The corrosion problems in all services are of a very generic nature and simply emanate from bad judgments, improper use of materials and processes, inadequate design engineering practices to meet corrosion science and engineering principles, and an overall lack of recognition of the fact that the corrosive environment has a severe impact on the performance of weapons systems.

The overwhelming consensus in the U.S. DoD is that there should be a new policy requiring prime contractors to improve material selection practices by paying more attention to corrosion resistance and engineering design concepts that prevent and/or control corrosion. Justification of additional acquisition cost to accommodate corrosion prevention that reflects on reduction of total ownership cost with some predictable metrics for savings should be acceptable. It is generally accepted that corrosion awareness training is vital for acquisition program managers of various military weapon systems so that they can implement corrosion prevention and control planning as an explicit part of performance-based acquisition and performance-based logistics.

Military Specifications and Standards

Norm Clayton, Naval Surface Warfare Center, Carderock Division

FOR ANY TYPE OF INDUSTRY, it is critical to have specifications and standards that set the requirements for products, ranging from raw materials, commodities, and materials of construction, to pieces of equipment and large-scale systems. Specifications and standards also define construction and fabrication processes and testing procedures. Although international voluntary consensus standards organizations, such as the International Organization for Standardization (ISO) and ASTM International (ASTM), fulfill the need for standards for a vast array of products, many industries have their own sets of specifications and standards based on the unique performance requirements for that industry. These are issued through their respective professional societies or by individual companies. The military organizations in each nation are no exception, as military equipment experiences many unique combinations of environmental exposure and war-fighting requirements that do not exist in other industries. This article provides a perspective on United States (U.S.) Department of Defense (DOD) specifications, standards, handbooks, and related documents and their role in corrosion prevention and control activities in the U.S. military.

Corrosion-control activities in the DOD deal with *weapons systems* (ships, aircraft, tanks, artillery, ground vehicles, guns, missiles, ammunition, etc.) and the *facilities* infrastructure needed to support them (buildings, piers, airfields, fuel and water tanks, piping, etc.). Both the weapons systems and facilities communities rely heavily on specifications and standards prepared and issued by the various service entities within the DOD, predominantly the Army, Navy (including the Marine Corps), and Air Force, either separately or jointly. The great majority of these documents are designated as *military* specifications, standards, and handbooks, with the designation prefix "MIL," although there are some designated as Department of Defense documents with the prefix "DOD."

Keeping specifications up-to-date can be costly. For this reason and others, there has been a large effort in the DOD over the past ten years to evaluate the suitability of commercial specifications and standards (such as ASTM) and adopt them where suitable, canceling the

associated military specification in the process. This effort has taken place under the broad initiatives of "Acquisition Reform" and the use of "commercial-off-the-shelf" (COTS) products. For ASTM specifications adopted by DOD, the phrase "This standard has been approved for use by agencies of the Department of Defense" appears under the title of the specification. This effort has been particularly successful in specifications for metallic materials; however, in other areas, such as paints and coatings, most military specifications have been retained by the various services. (For additional information on U.S. policy regarding federal agency use of voluntary consensus standards, refer to Public Law 104-113, "National Technology Transfer and Advancement Act of 1995," and the Office of Management and Budget (OMB) Circular A-119, "Federal Participation in the Development and Use of Voluntary Consensus Standards and in Conformity Assessment Activities" dated Feb 10, 1998.)

In addition to MIL, DOD, and ASTM specifications mentioned previously, the U.S. military corrosion-control communities make use of a wide variety of other standards to specify materials, coatings, sealants, inhibitors, abrasive blast media, and other chemical products, test methods, and manufacturing and production quality assurance (QA) requirements. These specifications may either be directly cited or be cited for specific requirements within a MIL specification. Notable examples include:

- Federal Specifications and Standards, and Commercial Item Descriptions issued by the U.S. General Services Administration (GSA) Federal Supply Service (FSS): specifications for a wide variety of products. One example, FED-STD-595B (Ref 1) is widely used within MIL specifications for paints and coatings to specify standardized color and gloss requirements
- SSPC—The Society for Protective Coatings: industrial painting surface preparation and painting requirements, specifications for abrasive blasting media, and certification programs for individuals and companies involved in industrial painting
- NACE International: coatings surface preparation standards issued jointly with SSPC,

recommended practices for fluid tank design and cathodic protection systems, and certification programs for individuals and companies involved in industrial painting

- ISO: industrial painting surface preparation QA requirements
- SAE International: SAE Aerospace Material Specifications (AMS) and SAE J Series Ground Vehicle Standards

The remainder of this article discusses specifications, standards, and related documents created and issued by the DOD.

Types of Documents and Designations

U.S. military organizations use a variety of documents to provide *requirements* and *guidance* for corrosion-control products and processes in both the design and construction of new weapon systems and facilities and the maintenance of these systems and facilities. The distinction between *requirements* and *guidance* is important, especially in a contracting application. Military specifications and standards provide requirements, whereas military handbooks can only provide guidance. The main types of documents are briefly described in this section.

Specifications. MIL-STD-961 (Ref 2) provides the format and content requirements for DOD specifications. The Foreword section of MIL-STD-961 summarizes the purpose of DOD specifications as:

The overall purpose of a specification is to provide a basis for obtaining a product or service that will satisfy a particular need at an economical cost and to invite maximum reasonable competition. . . . A good specification should do four things: (1) identify minimum requirements, (2) list reproducible test methods to be used in testing for compliance with specifications, (3) allow for a competitive bid, and (4) provide for an equitable award at the lowest possible cost.

Military specifications may include those that are widely used across several programs or applications and those that are unique to a single

program or system that would have little or no potential for use with other programs or systems. Most corrosion-control products, such as paints, coatings, sacrificial anodes, inhibitors, cleaners, sealants, and so forth would fall into the first category and represent the widest and most publicly known use of DOD specifications. Specifications that provide broader corrosion-prevention requirements for the design, testing, construction, or maintenance of a specific weapon system or facility fall into the second category and may be issued by a single branch of the DOD. There are two main categories of specifications: detail specifications, designated as "MIL-DTL," and performance specifications, designated as "MIL-PRF." These categories indicate how the requirements in the specification are stated. Older specifications may be designated as "MIL-X," where the "X" is a single letter representing the first word of the document title. All specification identifiers are being replaced with the DTL and PRF designations as they are revised. MIL-STD-961 (Ref 2) describes the types of specifications succinctly (note that a general specification must still be designated as a performance or detail specification):

Detail specification: A specification that specifies design requirements, such as materials to be used, how a requirement is to be achieved, or how an item is to be fabricated or constructed. A specification that contains both performance and detail requirements is still considered a detail specification. Both defense specifications and program-unique specifications may be designated as a detail specification.

Performance specification: A specification that states requirements in terms of the required results with criteria for verifying compliance, but without stating the methods for achieving the required results. A performance specification defines the functional requirements for the item, the environment in which it must operate, and interface and interchangeability characteristics. Both defense specifications and program-unique specifications may be designated as a performance specification.

General specification: A specification prepared in the six-section format, which covers requirements and test procedures that are common to a group of parts, materials, or equipments and is used with specification sheets. Specification sheets are documents "...that specify requirements and verifications unique to a single style, type, class, grade, or model that falls within a family of products described under a general specification."

Military specifications dealing with corrosion-control products and processes are too numerous to list here, and such a list would rapidly become obsolete. Electronic searching of the on-line databases and sources of specifications described

later in this article is the best way to find a specification of interest.

Qualified Products List (QPL). A detail or performance specification may or may not require that products be submitted to a qualifying activity in order for them to be listed on a QPL. When a QPL is not required, frequently there is an alternative requirement to pass first article testing or inspection. When a specification requires that products be listed on a QPL, it will be described in one of the first paragraphs in Section 3 "Requirements" in the specification. (See the section, "Format of Specifications" below.) The QPL for a product specification will have the same number as the parent specification, with a suffix to indicate the revision number of the QPL. For example, the tenth edition of the QPL for notional specification MIL-PRF-123 would be designated as QPL-123-10. A QPL listing will contain:

- Government designation: the type, class, grade, and so forth of the product as defined by the parent specification
- Manufacturer's designation: the commercial product name used by the manufacturer to identify the product
- Test or qualification reference: a citation for the test report or other document used to place the product on the QPL
- Manufacturer's name and address: self-evident

Standards. MIL-STD-962 (Ref 3) provides the format and content requirement for military standards. Military standards provide requirements that are to be used when the standard is specifically cited in a contract, purchase order, or other specification. Just because an active military standard exists does not indicate that it automatically applies to any military weapon system or facility; it must be specifically

invoked. Table 1 lists active military standards pertaining to corrosion and coating as of the date of this article (2005). The "source" column indicates the lead service activity that is responsible for maintenance of the standard. In some cases, the scope of a standard may be limited to a single branch of the military, such as MIL-STD-1303 and the Navy. In others, the standard may be used and collaboratively updated by all branches of the military, such as MIL-STD-810.

For corrosion-prevention applications, Table 1 shows that there are three main categories of military standards:

- Standards that cover specific processes for the application of a type of coating or other surface treatment. MIL-STD-865, MIL-STD-1501, and MIL-STD-2138 are examples.
- Standards that provide a set of requirements for coatings or other corrosion-control methods to be used on certain types of military systems or facilities. MIL-STD-171, MIL-STD-1303, and MIL-STD-7179 are examples. These standards will themselves contain requirements that cite a variety of specific surface preparation and coating treatments according to commercial industry or other military specifications.
- Test methods that are to be used to evaluate or qualify military systems, equipment, or facilities, or to qualify specific types of products. MIL-STD-810, MIL-STD-2195, and MIL-STD-3010 are examples. Note that when a military standard for test methods is cited in a specification, specific test methods within the standard and their acceptance criteria generally must also be specified.

There are other miscellaneous standards in Table 1 that do not fall into the general categories described in the preceding list, such as

Table 1 Active military standards pertaining to corrosion and coating

Preparing organization	Number	Date(a)	Title
Army	MIL-STD-171E	June 23, 1989	Finishing of Metal and Wood Surfaces
Air Force	MIL-STD-810F	May 5, 2003	Environmental Engineering Considerations and Laboratory Tests
Air Force	MIL-STD-865C	Nov 1, 1988	Selective (Brush Plating), Electrodeposition
Air Force	MIL-STD-868A	March 23, 1979	Nickel Plating, Low Embrittlement, Electrodeposition
Air Force	MIL-STD-869C	Oct 20, 1988	Flame Spraying
Air Force	MIL-STD-889B	May 17, 1993	Dissimilar Metals
Navy	MIL-STD-1303C	April 11, 1994	Painting of Naval Ordnance Equipment
Air Force	MIL-STD-1501C	April 2, 1990	Chromium Plating, Low Embrittlement, Electrodeposition
Air Force	MIL-STD-1503B	Nov 13, 1989	Preparation of Aluminum Alloys for Surface Treatments and Inorganic Coating
Air Force	MIL-STD-1504B	June 8, 1989	Abrasive Blasting
Air Force	MIL-STD-1530B	Feb 20, 2004	Aircraft Structural Integrity Program (ASIP)
Navy	MIL-STD-1687A	Sept 23, 1994	Thermal Spray Processes for Naval Ship Machinery Application
Navy	MIL-STD-2073	May 10, 2002	Standard Practice for Military Packaging
Navy	MIL-STD-2138A	Aug 29, 1994	Metal Sprayed Coatings for Corrosion Protection Aboard Naval Ships (Metric)
Navy	DOD-STD-2187	Aug 20, 1987	Chemical Cleaning of Salt Water Piping Systems (Metric)
Navy	MIL-STD-2195A	Dec 17, 1993	Detection and Measurement of Dealloying Corrosion on Aluminum Bronze and Nickel-Aluminum Bronze Components, Inspection Procedure for
Army	MIL-STD-3003A	July 7, 2003	Vehicles, Wheeled: Preparation for Shipment and Storage of
Navy	MIL-STD-3010	Dec 30, 2002	Test Procedures for Packaging Materials
Navy	MIL-STD-7179	Sept 30, 1997	Finishes, Coatings, and Sealants, for the Protection of Aerospace Weapons Systems

(a) Base date of primary document; validation notices may be dated later

MIL-STD-889, MIL-STD-1530, and MIL-STD-3003. MIL-STD-889 is notable among them and is described in more detail later in this article.

Handbooks. MIL-STD-967 (Ref 4) provides the format and content requirement for military handbooks. Table 2 lists military handbooks dealing with corrosion control or coatings that are still active as of the date of this article (2005). Unlike military specifications and standards, military handbooks have evolved to become documents that are to be used for guidance purposes only, especially in the context of a DOD contract specification for equipment. If this is not clearly stated in the text of the handbook, then a standardized notice has been added to the cover page of the handbook, such as the one shown below for MIL-HDBK-1568:

NOTE: MIL-STD-1568B(USAF) has been re-designated as a handbook and is to be used for guidance purposes only. This document is no longer to be cited as a requirement. For administrative expediency, the only physical change from MIL-STD-1568B(USAF) is this cover page. If cited as a requirement, contractors may disregard the requirements of this document and interpret its contents only as guidance.

Despite being designated as guidance documents only, military handbooks dealing with corrosion prevention, and coating and related processes still may have a variety of uses, such as being used as basic reference documents and readily available training resources for military personnel responsible for maintenance of systems and facilities. However, these documents are not updated and kept up-to-date with current policies and technology as frequently as the more actively used military specifications and standards.

Military Drawings. While military specifications and standards as described previously are used by the U.S. military services to specify most corrosion-control products and processes, there is another significant class of documents broadly characterized as military drawings. These are detailed drawing sheets for piece parts of mechanical or electrical hardware and other items, which include dimensions, materials and finishes, and other technical manufacturing characteristics, and provide an accompanying part number system. These drawings may often be used to support a parent procurement specification. Examples of the various types of military drawings include:

- AN: Air Force-Navy Aeronautical Standard Drawing
- DESC: Defense Electronics Supply Center Drawings
- MS: Military Standard Drawing, or Military Specification Sheet

Service-Specific and Other Documents. In addition to the aforementioned documents, each branch of the DOD has an assortment of corrosion-control and coating documents that

variously provide policy requirements or recommended guidance specific to the issuing branch of the DOD. These include documents termed Technical Manuals (TM), Technical Orders (T.O.), Technical Publications, Army Regulations (AR), Technical Repair Standards (TRS), Standard Maintenance Items, Project Peculiar Documents (PPD), and Preservation Process Instructions (PPI), to name a few. A great number of these documents are intended to convey corrosion-prevention and repair requirements to equipment or facility operating and maintenance personnel, whether they are uniformed service personnel or contracted companies. However, many are also used in new procurements of systems or facilities.

The U.S. Army Corps of Engineers and the Naval Facilities Engineering Command also maintain a set of technical manuals and guide specifications (GS) pertaining to corrosion prevention and control in the construction and maintenance of facilities. A number of these are listed in Table 3. For additional information on

these specifications, refer to MIL-STD-3007 (Ref 5).

Format of Specifications

Like commercial industry standards such as ASTM, military specifications are required to follow a standard format. Military specifications use a six-section format using well-defined requirements in MIL-STD-961 (Ref 2). The six numbered sections and their content are briefly described in this section.

1. Scope: provides a concise description or abstract of what the specification covers, as well as any categories and subcategories of use or types of material, using terms such as Type, Class, Grade, or other distinction. A relatively new requirement for military specifications is that if the specification describes more than one part or item, and if U.S. Federal Supply System National Stock Numbers (NSNs) are to be

Table 2 Active military handbooks pertaining to corrosion and coating

Preparing organization	Number	Date(a)	Title
Army	MIL-HDBK-113C	April 24, 1989	Guide for the Selection of Lubricants, Functional Fluids, Preservatives and Specialty Products for Use in Ground Equipment Systems
Army	MIL-HDBK-205A	July 15, 1985	Phosphate and Black Oxide Coating of Ferrous Metals
Navy	MIL-HDBK-267A	March 3, 1987	Guide for Selection of Lubricants and Hydraulic Fluids for Use in Shipboard Equipment
Air Force	MIL-HDBK-310	June 23, 1997	Global Climatic Data for Developing Military Products
Army	MIL-HDBK-341	Feb 27, 1998	Coating, Aluminum and Silicon Diffusion, Process for
Army	MIL-HDBK-506	April 10, 1998	Process for Coating, Pack Cementation, Chrome Aluminide
Army	MIL-HDBK-509	Dec 7, 1998	Cleaning and Treatment of Aluminum Parts Prior to Painting
Army	MIL-HDBK-729	Nov 21, 1983	Corrosion and Corrosion Prevention Metals
Army	MIL-HDBK-735	Jan 15, 1993	Material Deterioration Prevention and Control Guide for Army Materiel, Part One, Metals
Navy	MIL-HDBK-1004/10	Jan 31, 1990	Electrical Engineering Cathodic Protection
Navy	MIL-HDBK-1015/1	May 31, 1989	Electroplating Facilities

assigned to the items, then the scope section will provide the means for creating a Part Identification Number (PIN) based on the specification number.

2. Applicable Documents: lists all of the documents referenced in sections 3, 4, and 5 of the specification and the source that someone can use to obtain the documents.

3. Requirements: describes all of the requirements that the item(s) must meet in order to be acceptable under the specification. For each requirement, there should be an accompanying verification, or test cross-referenced and described in section 4. The type of specification—that is, detail, performance, or general—will determine the detail or performance nature of the requirements.

4. Verification: describes all of the tests or inspections that are needed to verify that the item(s) meets the requirements in section 3. The inspections or tests may be classed as first article, conformance, or qualification. This section may also provide sampling requirements and define the size of inspection lots.

5. Packaging: MIL-STD-961 provides a standard paragraph that must be used, stating that packaging shall be described in the contract or purchase order.

6. Notes: The notes in section 6 are only for general information or explanation. There is frequently an “intended use” paragraph in this section that can help a potential user of the specification determine which of the various types, classes, or grades of material covered by the specification is best suited to meet their needs. MIL-STD-961 now also requires the *Intended Use* paragraph to indicate what causes the product to be military-unique.

In addition to the aforementioned sections, some specifications may also have appendices that may or may not be mandatory parts of the specification. Frequently, appendices are used to describe some unique test or test apparatus required by section 4, when there is no suitable equivalent industry standard test method.

Sources of Documents

The definitive source for DOD and military specifications is through the Department of Defense Single Stock Point (DODSSP) for Military Specifications, Standards and Related Publications. The DODSSP is managed by the Document Automation and Production Service (DAPS), Building 4/D, 700 Robbins Ave., Philadelphia, PA 19111-5094. Documents in the DODSSP collection include:

- Military performance and detail specifications
- Military standards
- DOD-adopted non-government industry specifications and standards
- Federal specifications and standards and commercial item descriptions
- Data item descriptions (DID)
- Military handbooks

- Qualified products lists (QPL) and qualified manufacturer’s lists (QML)
- U.S. Air Force and U.S. Navy aeronautical standards and design standards
- U.S. Air Force specifications bulletins

The Department of Defense Index of Specifications and Standards (DODISS) contains the complete list of documents in the DODSSP collection. This reference publication and all of the above documents are available to subscribers of an on-line database known as the “Acquisition Streamlining and Standardization Information System” (ASSIST). The ASSIST database is considered to be the official source of DOD specifications and standards. The documents are provided electronically in Adobe Portable Document Format (PDF). The ASSIST web page (2005) is <http://assist.daps.dla.mil/online/start>.

There is a complementary web site to ASSIST that has fewer features and only allows access to the electronic PDF format of the specifications. This site does not require an account or password and may be quicker. This web page is <http://www.assistdocs.com>.

In addition to being available through the ASSIST on-line database described previously, numeric and alphabetical lists of U.S. federal specifications, standards, and commercial item descriptions can be researched at the web site of the General Services Administration (GSA) Federal Supply Service (FSS): <http://apps.fss.gsa.gov/pub/fedspecs>.

Another popular source of DOD, Federal, and many other types of commercial and industry standards and specifications is the Information Handling Services (IHS), 15 Inverness Way East, Englewood, CO 80112. This is a commercial paid subscription service. For more information, see their web site at <http://www.ihsinc.com/index.html>.

Notable Specifications, Standards, and Handbooks

While the number of military specifications, standards, and handbooks pertaining to corrosion control and coatings are slowly dwindling in favor of commercial standards, there are some that will continue to have significant use for years to come, as reference, guidance, or requirements documents. Several of those that find widespread use are described in this section.

MIL-HDBK-729: Corrosion and Corrosion Prevention; Metals. This is a 251-page general reference document that is freely available to DOD personnel, from equipment and facility maintainers, to designers and engineers, to program managers. Its primary value is as an educational tool tailored to corrosion in military equipment. It describes corrosion principles, the influences of different types of operating environments, and most of the common (and uncommon) forms of corrosion. It also discusses

corrosion in each of the major alloy groups and corrosion-prevention techniques to match the different forms of corrosion discussed. Laboratory and field corrosion testing are also discussed. While this handbook has many figures and technical literature references, it is not intended to provide quantitative design data such as corrosion rates.

MIL-HDBK-310: Global Climatic Data for Developing Military Products. On the surface, this handbook does not purport itself to be a document concerned with corrosion control. However, it provides worldwide climate data that can affect corrosion and material performance, such as temperature, humidity, rainfall, and ozone concentrations. The data are presented for defined climatic regions such as “basic,” “hot,” “cold,” and “coastal/ocean” and provides extremes and frequencies of occurrence. The data are intended for use in engineering analyses to set requirements, develop, and test military equipment. Therefore, it is used to support the use of MIL-STD-810, described below.

MIL-STD-810: Environmental Engineering Considerations and Laboratory Tests. This is an important, complex, and lengthy (549 pages) standard that is widely used in the acquisition of DOD equipment. (Equipment is often called “materiel” in military terms.) The standard was extensively revised in the “F” revision in 2000 and divided into two complementary parts. As described in the Foreword, the emphasis of these two parts is on “. . . tailoring a materiel item’s environmental design and test limits to the conditions that the specific materiel will experience throughout its service life, and establishing laboratory test methods that replicate the effects of environments on materiel rather than trying to reproduce the environments themselves.” Part One describes an Environmental Engineering Program (EEP) that focuses on the selection, design, and criteria for testing equipment under the specific environmental conditions, or stresses it is expected to be exposed to in service. A key element in Part One is providing guidance on the tailoring, or customizing, of the total program and the required testing. Part Two contains the laboratory test methods, which in turn provide for various degrees of tailoring depending on the specific test. The test methods cannot be specified simply by name or number; the equipment specification that invokes MIL-STD-810 must also provide the details of the test tailoring, such as frequency, cycle, or dwell times, temperatures, and so forth, and the associated acceptance criteria. Table 4 lists the test methods that are currently included in Part Two of MIL-STD-810.

MIL-STD-889: Dissimilar Metals. Many well-meaning writers of military equipment procurement specifications include a requirement that the design shall avoid dissimilar metal couples and galvanic corrosion or shall take steps to mitigate them. Unfortunately, in many cases that language is all that is used, leaving the definition of what exactly constitutes a dissimilar

metal couple subject to the interpretation of the contractor or designer. Sometimes a minimum voltage potential difference between the metals is cited in the specification, above which a couple shall be considered to be dissimilar. However, experienced corrosion engineers know that it is not simply the potential difference on a galvanic series (typically only provided for seawater) that determines whether significant galvanic corrosion will be a design risk. Factors such as the anodic to cathodic area ratio (the "area effect" discussed elsewhere in this Volume), polarization and passivity, the nature of the electrolyte, and the temperature all should be considered. While not a substitute for a design review by a corrosion professional, MIL-STD-889 is

sometimes cited in a contract specification to provide a better definition of dissimilar metals and to provide guidance for corrosion-protection methods that can be used when galvanic couples cannot be avoided. The dissimilar metals charts in *ASM Handbook*, Vol 13B, 2005, are based on this standard.

MIL-DTL-53072: Chemical Agent Resistant Coating (CARC) System; Application Procedures and Quality Control Inspection. A unique military requirement for the exterior coatings on ground equipment is that they be able to provide corrosion protection and camouflage, while resisting the absorption of harmful chemical warfare agents. Furthermore, these coatings should facilitate cleaning with caustic and other types of decontaminating solutions in the event that the equipment is exposed to these agents. The Army and the Marine Corps are the primary users of ground equipment, which includes tactical combat vehicles (tanks, artillery, armored personnel carriers, etc.), and logistics and engineering support equipment (trucks, trailers, cranes, bulldozers, etc.). However, both the Air Force and Navy also use this equipment, so the CARC coating system finds wide application. There are a number of pretreatments and coatings that comprise the total CARC system, which generally includes epoxy primers and polyurethane topcoats. MIL-DTL-53072 is the specification that covers the general requirements for application and inspection of the CARC system. From the scope section of the specification, it also:

... is intended for use as a guide in selection of the appropriate materials and procedures, and as a supplement to information available in ... referenced cleaning, pretreating, and coating specifications. The document also includes information on touchup/repair, health and safety guidelines, environmental restrictions, national stock numbers (NSN) for CARC and CARC-related materials, and application equipment and techniques.

Department of Defense Corrosion Policy

In 2003, the DOD initiated a new corrosion prevention and control policy aimed at "... implementing best practices and best value decisions for corrosion prevention and control in systems and infrastructure acquisition, sustainment, and utilization" (Ref 6). This policy requires that all major new U.S. military acquisition programs create a corrosion-control strategy and a "Corrosion Prevention and Control Plan" (CPCP). To accompany this policy, a planning guidebook has also been created by a team of corrosion-control professionals in DOD (Ref 7). This guidebook, and other information related to the DOD corrosion-prevention policy, can be found at the web site www.DoDcorrosionexchange.org.

Corrosion Control for Military Facilities

Ashok Kumar and L.D. Stephenson, U.S. Army Engineer Research and Development Center (ERDC)
Construction Engineering Research Laboratory (CERL)
Robert H. Heidersbach, Dr. Rust, Inc.

CORROSION DEGRADATION is the most costly and pervasive maintenance and repair problem in the U.S. Army. Studies have shown that the annual corrosion-related costs at U.S. Army installations are about 13 to 15% of the Maintenance of Real Property and Minor Construction costs. About half of these corrosion-related costs could be attributed to structural, electrical, and mechanical components in buildings and the other half to utilities. Anecdotal evidence suggests that this percentage has not increased with the aging of facilities since older facilities are being replaced with newer facilities incorporating improved corrosion-control technologies.

Public Law addresses "Military equipment and infrastructure prevention and mitigation of corrosion" and requires the Secretary of Defense to "develop and implement a long-term strategy to reduce corrosion and the effects of corrosion on the military equipment and infrastructure of the Department of Defense (DoD)" (Ref 1).

Components susceptible to corrosion include building structural components and utilities (that will be privatized at some installations) such as metal buildings, metal roofing, aircraft hangars, outdoor electrical sheet metal for air conditioners, electrical boxes, underground pipes (gas, water, steam, high-temperature hot water), pipes in buildings, boilers, chillers, condensate lines, water storage tanks, and so forth.

Title 10 of the Uniform Service Code, Section 2228 directs the DoD to actively pursue a department-wide approach to combat corrosion (Ref 1). In response to Congressional interest, the Secretary of Defense has designated the creation of an Office of Corrosion Policy and Oversight, and the Office of the Secretary of Defense (OSD) Corrosion Prevention and Control Program for weapons and facilities was initiated to demonstrate and implement emerging corrosion-control technology that can save up to 30% of the corrosion-related costs (Ref 2). Corrosion-control technologies being implemented under this program include:

- Coatings
- Cathodic protection (CP)
- Advanced (corrosion-resistant) materials selection and design

- Water treatment
- Remote corrosion assessment and management

The major benefit of the implementation of these corrosion-control technologies at Army installations is the extension of the service life of buildings and other structures.

Information presented here is from a variety of Army and Air Force installations throughout the United States and focuses on selected examples of corrosion and corrosion-prevention projects for infrastructure that have recently been completed or are currently underway. Many of the case studies are taken from the research program in which the authors have participated or have direct knowledge.

The Environment

Facilities and equipment operated by the U.S. Army are exposed to a wide variety of environmental conditions, including soils, waters, or atmospheres of varying corrosivity. The various types of resulting corrosion can create a costly maintenance and repair burden while adversely affecting Army operations. The major types of corrosion phenomena are (a) uniform corrosion, (b) pitting attack, (c) galvanic corrosion, (d) environmentally induced delayed failure (e.g., stress-corrosion cracking), (e) concentration-cell corrosion, (f) dealloying, (g) intergranular corrosion, and (h) various forms of erosion corrosion. It is not at all unusual for more than one form of corrosion to act on the same structure at the same time. For example, the steel components in a steam-heating system can be simultaneously subjected to conditions that cause uniform corrosion, pitting attack, galvanic corrosion, and the cavitation form of erosion corrosion.

It is important to understand that the characteristics of soils, waters, and atmospheres at Army installations can be expected to vary greatly and that this variation has important implications for corrosion-mitigation strategies. No two installations have identical environmental conditions, and corrosion-promoting conditions can even be expected to vary within

the boundaries of a given installation. For example, soils at an inland installation may be even more naturally corrosive than the chloride-containing soils along an ocean. Many island and peninsular locations have atmospheric conditions that are severely corrosive on the windward sides but relatively mild on the leeward sides. There are also many inland locations where the atmosphere can be unusually aggressive due to the proximity of facilities such as paper mills or power plants burning high-sulfur coal. Also, the use of road salts to melt snow and ice in the higher latitudes is a contributing factor to corrosion of steel structures. For example, Fort Drum is an inland location in the northern United States, where road salts led to premature corrosion of steel doors, which have since been replaced by fiberglass-reinforced plastic (FRP).

Although protective coatings are an effective option for mitigating many varieties of atmospheric corrosion, they are basically useless in steam-heating systems. Similarly, methods for altering the internal environments in a steam-heating system to mitigate corrosion of the boiler, pipes, and heat exchangers should *not* be considered for corrosion control on the soil-side surfaces of the steel conduits and casings that house the steam and condensate lines. In the latter case, effective corrosion control can be achieved only by protective coatings used in conjunction with CP. However, neither of these corrosion-control techniques will work properly if wet and chemically aggressive insulation contacts the inside surfaces of the casings/conduits or the outside surfaces of the steam and condensate pipes.

References on corrosivity of soils, waters, and atmospheres at various military locations are available from websites maintained by the Army Corps of Engineers, Engineer Research and Development Center, Construction Engineering Research Laboratory (ERDC-CERL).

Case Studies

These case studies illustrate typical examples of the types of corrosion problems found on military installations. Most of the problems

encountered are typical of those found on civilian installations, although some problems are unique to the military.

Fences. Secure fencing is more important at military installations than at many other locations. Sensitive equipment and ammunition is often stored near roads and other access points where military personnel and their dependents travel on a frequent basis. Airfields, firing ranges, and ammunition storage facilities are typical areas where fencing security is particularly important. Not only does the low-alloy steel chain-link fencing corrode, but the posts often show more corrosion of the structural steel, especially in severe environments, such as coastal atmospheres.

Replacement of these fences is expensive, and a typical military installation will have many miles of such fencing. Polyvinyl chloride (PVC)-clad galvanized steel chain-link fencing should be used in severely corrosive atmospheres. Posts, gates, and their accessories should have a coating system consisting of 27 mg of zinc per square centimeter (0.9 oz of zinc per square foot), a minimum of 76 μm (0.3 mil) of cross-linked polyurethane acrylic, and a minimum of 178 μm (7 mil) vinyl topcoat. For severely corrosive atmospheric conditions, the topcoat should be 381 μm (15 mils) thick. Chain-link fence systems may be fabricated from anodized aluminum alloys provided they have adequate strength (Ref 3, p 31).

Exfoliation of an aluminum guardrail (a form of fencing) on a public highway passing through a military installation can be caused by the rubbing of the aluminum against the support bolt. Fretting corrosion that starts at this location is often due to the daily expansion and contraction of the aluminum causing it to rub against the fixed bolt.

Structural steel is used for many purposes on military installations including buildings, bridges, electric utility poles, and support structures for various types of equipment. Figures 1 and 2 show an electric utility light pole within the confines of a wastewater treatment plant (WWTP) at an Army installation. The pole corroded near the base as well as along the vertical portions of the pole. Causes of the corrosion shown in these pictures include the humid environment and the attack of hydrogen sulfide from the WWTP. Poor surface preparation prior to application of protective coatings, shipping and handling damage prior to erection, and abrasion and submersion of the pole when water and sand or gravel accumulate near the base of the pole may have exacerbated the corrosion. Ultraviolet (UV) degradation of protective coatings is also a concern, even though modern protective coatings are more resistant to UV degradation. In many cases, it is possible to remove the deteriorated coating by sandblasting and, after proper surface preparation, recoat the surface with coal-tar epoxy coatings to protect against future corrosion (Ref 3, p 47).

It is also noted that poles, standards, and accessories (shafts, anchor belts, bracket arms,

and other hardware) for such applications should be galvanized steel for relatively nonaggressive atmospheres. In more aggressive environments, such as within the confines of a WWTP, the same components should be aluminized steel, type 304 stainless steel, or type 201 stainless steel.

The highest structural loading on poles and guardrails occurs near the base of the structure where the maximum bending moment is located. Thus, corrosion on structural steel, which is commonly more pronounced near the base, occurs where the remaining metal will have the highest mechanical loading.

Figure 3 shows a guardrail that must be replaced because of corrosion damage. Figure 4 is a close-up of a guardrail that was attached to a concrete curb. The steel rail was inserted into a hole in the concrete and then soldered in place using a lead-base low-melting-point alloy. Removal of the lead alloy would create a major

hazardous waste disposal problem. Current guidelines for dealing with lead in construction such as that shown in Fig. 3 allow the material to remain in place. Having identified the lead alloy prior to guardrail removal, the replacement was redesigned, so that the attachment was left in place and the new guardrail was bolted to the concrete curb. In early 2004, a positive chemical analysis to identify lead use in the attachment cost only a small fraction ($<0.04\%$) of the cost for lead hazardous waste disposal of the lead. Current specifications require that guardrails and handrails be fabricated from a suitable anodized alloy such as 6061-T6 (Ref 3, p 37).

Metal Roofing. Many military installations have "temporary" buildings built during times when expansion of facilities takes priority over quality of construction. Many of these structures then remain in service for decades beyond their design life. Corrosion of sheet metal roofing is common on these buildings and the corrosion of

Fig. 1 Corroded low-carbon steel light pole due to corrosive atmosphere at a wastewater treatment plant on a military installation

Fig. 2 Close-up of corrosion at the base of the pole shown in Fig. 1

Fig. 3 Corrosion pattern on a mild steel pedestrian guardrail at a military installation exposed to a coastal atmosphere

Fig. 4 Close-up of the base of the vertical pole shown in Fig. 3. Note that the pole was soldered in place using a lead-base low-melting-point alloy.

roofs is a continuing concern. Coated galvanized steel is not appropriate for many coastal or severely corrosive atmospheres. The preferred material for roofing and siding is type 2 aluminized steel, with factory-applied oven-baked fluoropolymer enamel coatings applied to a minimum thickness of 25 μm (1 mil), although thicker coatings are preferred when the coatings are subjected to wind-blown sand environments, such as in the Middle East.

Military specifications for metal roofs and sidings have recently been updated by specifying ASTM D 5894, "Standard Practice for Cyclic Salt Fog/UV Exposure of Painted Metal, (Alternating Exposures in a Fog/Dry Cabinet and a UV Condensation Cabinet)" for 2016 h to evaluate candidate galvanized and zinc-aluminum alloys on steel, as well as the use of polymeric coatings (Ref 4). Polyvinylidene fluoride (PVF2) coated and silicone-modified polyester (SMP) coated galvanized and zinc-aluminum alloys have been found to pass these tests and are acceptable for metal roofing. The coatings on both materials were 25 μm (1 mil) thick (Ref 5). Long-term appearance of PVF2-coated zinc-aluminum or galvanized steel substrates, as evaluated by the ASTM D 5894 test, is excellent. PVF2 is only slightly better than SMP. Galvalume (Zn-55 Al) coatings performed slightly better than galvanized coatings (Ref 5).

Doors and windows are locations where corrosion is frequently more severe than walls, roofs, and other components of a building. Figures 5 and 6 show corroded doorways near a wastewater treatment plant on a military installation. The replacement of a few doors is a fairly inexpensive project. However, since there are large numbers of doors on military installations any cost savings due to the use of more corrosion-resistant materials can result in major savings on maintenance costs. Fiberglass-reinforced plastic doors with type 304 stainless steel handles and kickplates are viable corrosion-

resistant alternatives to steel doors, and they are commercially available in a variety of styles and colors, with special features such as being fireproof and resistant to certain industrial chemicals. If steel doors and frames are required (e.g., for security reasons), they should be aluminized with a factory-applied oven-baked fluoropolymer enamel coating. The benefits of implementing corrosion-resistant building components composed of materials such as FRP or aluminized steel and stainless steel hardware are extended service life, reduced maintenance cost, and enhanced appearance (Ref 3, p 31).

Electrical/Mechanical Systems. Heating, ventilation, and air conditioning (HVAC) systems are major sources of corrosion problems on military installations. Many, but not all, of these systems are located inside buildings. Channeling in a steam condensate return pipeline on a military installation (Fig. 7) is caused by acidic condensate. Condensate lines, like most liquid return lines, normally run only partially full, and corrosion occurs if inhibitors do not prevent pH shifts that cause the condensate to become acidic. Leakage of air (oxygen and carbon dioxide) into the return line causes this corrosion. (See the article "Corrosion in the Condensate-Feedwater System" in this Volume and "Corrosion Inhibitors in the Water Treatment Industry" in *ASM Handbook*, Vol 13A, 2003.) Military installations are limited in the choice of the chemicals they can use for treating steam/condensate systems, because their steam, unlike the steam in many industrial applications, is often used for cooking and other applications where toxic corrosion inhibitors cannot be used. Emerging corrosion-control programs are demonstrating nontoxic "green" corrosion inhibitors for use in steam systems at military installations. Industrial and commercial utility plants often use on-line monitoring and control systems to track water chemistry parameters and control chemical treatment and blowdown.

Many of these systems, such as pH and conductivity controllers, are relatively easy to use and maintain. This technology reduces manpower for system monitoring and control of corrosion/scale, increases life cycle of heating and cooling systems, and reduces the use of environmentally sensitive chemicals (Ref 6).

Many military installations transport steam long distances. Steam leaked under the insulation may condense and wet the insulation, leading to additional corrosion. Corrosion under insulation is very hard to detect (Ref 7, 8). While corrosion can, and does, occur on the outside of steam lines, it is much more likely to occur on the outside of condensate return lines. Since condensate lines operate below the boiling point, water is much more likely to accumulate on the metal pipe surfaces underneath insulation on condensate lines than it is on steam lines. Concentration of salts caused by evaporation of moisture underneath the insulation can lead to stress-corrosion cracking on the outside of condensate lines. Similar problems occur on water lines. The corrosion shown on the pipe in Fig. 8 was caused by degradation of the elastomeric insulation used to protect the outside of the pipe. Neither the metal pipe nor substrate had been coated. Guidelines have been developed on how to specify and install insulation to prevent this

Fig. 5 Corroded metallic doorway at a military installation water treatment plant due to chlorine atmosphere

Fig. 7 Channeling ("grooving") of condensate return line due to carbon dioxide leaking into steam/condensate system

degradation. They include (a) avoiding coupling dissimilar metals together in the presence of conductive moisture and (b) properly sealing insulation against the intrusion of humid air.

Fuel Transport and Storage Systems. The most viable option for mitigating corrosion of underground fuel storage tanks exposed to aggressive soils is a combination of protective coatings and CP. The preferred system for underground fuel storage tanks ($\geq 76,000$ L, or 20,000 gal) is horizontal double-wall tanks with full 360° secondary containment, glass-fiber-reinforced polyester tanks and accessories manufactured according to ASTM D 4021-81 (Ref 9). Underground fuel storage tanks can be installed at service stations using horizontal double-wall steel tanks that are coated (a)

Fig. 8 Corrosion of hot water line after insulation was degraded by water intrusion

internally with epoxy or urethane and (b) externally with high-performance coal-tar epoxy, or fiberglass/resin for maximum protection in very aggressive soils. Steel pipes should be similarly coated. Both the tanks and pipes should be provided with CP (Ref 3, p 78–79).

Chemical Process Equipment. Most military installations have limited chemical processing responsibilities, and the numbers of chemically trained personnel, both military and civilian, are smaller than in many other industries. Nonetheless, chemical processing equipment, and the corrosion failures related to it, are present on many military installations.

Figure 9 shows a corroded valve control handle at a wastewater treatment plant. The economics of alternative materials and the proper selection of these materials are beyond the background of the engineering organizations on many military installations. Stainless steels and other corrosion-resistant alloys are an available economical alternative that can be implemented to minimize the costs and disruption associated with corrosion failures such as those shown in Fig. 9. Other recommendations for mitigation of corrosion at wastewater treatment plants include:

- The use of petrolatum tape coatings for exposed pipes/valves
- Restoration coatings for deteriorated concrete for large structures such as clarifiers
- Corrosion-resistant metals and polymers for electrical junction boxes
- Polymeric gaskets not susceptible to embrittlement

Fig. 9 Corroded control handle exposed to corrosive atmosphere at a wastewater treatment plant on a military installation

- Cathodic protection for immersed steel components, such as rake arms and metal weirs in clarifiers

Emerging Corrosion-Control Technologies

Protective Coatings and Linings. Many new coatings are under development in the civilian sector and are being applied on military installations. Figure 10 shows a potable water pipe contaminated by rusty water that services an Air Force Base hospital. It was repaired in situ by draining, drying, and abrasively blasting the interior followed by pumping an epoxy slug through the pipe, as shown in Fig. 11. The coating application to a thickness of 350 to 500 μm (14 to 20 mils) was successful in rehabilitating the piping system in question with a cost savings of more than 30% over the cost of replacement piping. The in situ pipe coating technology accommodates a variety of pipe lengths, diameters (> 12.5 mm, or 0.5 in., diameter), bends, and materials. It eliminates corrosion and scaling, and lead and copper dissolution in potable water and energy piping systems, and restores full water pressure.

Figure 12 shows a deteriorated protective coating for a water deluge tank (part of a fire-suppression system at an Army airfield), where

Fig. 10 Corroded water pipe contaminates water that services an Air Force Base hospital

Fig. 11 In situ epoxy coating applied to the inside of the pipe shown in Fig. 10 after abrasive blast cleaning

the original lead-base paint was overcoated to dry film thicknesses of about 190 μm (7.5 mils) with test coatings of two moisture-cured polyurethanes. Both overcoating systems performed well over a winter test period with no evidence of blistering, spalling, or peeling. This entire tank was then repainted with one of the moisture-cured polyurethane systems. The coating exhibited no evidence of cracking or peeling, no evidence of rust, and no evidence of corrosion for the past 4 years (Ref 10).

The benefit of implementing innovative overcoating technology, such as applications of moisture-cured polyurethane, is to extend the service life of steel structures, reduce maintenance cost, improve the performance of equipment, and eliminate the expense of removing lead-base paint. Overcoating can be significantly less expensive than other maintenance practices, particularly when the pre-existing coating contains lead or other hazardous materials. Deluge tanks are mission critical equipment at an Army airfield, and flights are grounded if these systems are not operable.

Cathodic protection is one of many conventional corrosion-control techniques used at DoD installations. Most CP systems are installed by civilian contractors. Since engineers at most DoD installations have limited experience in CP, it is important that agency-wide guidance is readily available and up-to-date.

Industry-standard storage tanks are widely used for storing liquids underground. They have factory-installed CP systems. Unfortunately, some tanks were provided (as recently as March 2003) with sacrificial zinc anodes for use on tanks in all types of soil and sacrificial magnesium anodes for use only in high-resistivity soil (see the article "Cathodic Protection" in *ASM Handbook*, Vol 13A, 2003). This application of zinc and magnesium anodes was contrary to conventional wisdom for the use of these anodes. Conventional practice allows magnesium anode usage in all soil conditions and the use of zinc anodes only in soils having very low resistivity (Ref 11). It is necessary that engineers at military installations be sufficiently familiar with these types of systems so that they can spot misuse of anodes or inappropriate CP practices. Obtaining

instruction on these practices is a needed part of their training.

Impressed-current CP is used to prevent internal corrosion of the water side of potable water storage tanks by applying a negative potential to the structure from an external source. Remote monitoring units (RMUs) are being used to demonstrate the reliability of CP in controlling corrosion of elevated water towers. Cathodic protection systems for water storage tanks must be periodically tested in order to ensure proper performance (Ref 12). Remote monitoring units provide the ability to continuously monitor CP system performance data from remote locations using modem-equipped personal computers. Figure 13 shows a CP rectifier coupled to a RMU. Elevated water towers are frequently the largest structures at military installations that use impressed-current CP.

In the past, large and heavy iron-silicon and graphite anodes were required for CP systems, which made the anode vulnerable to debris and ice damage and prone to field installation problems, leading to numerous electrical shorts in the system. Ceramic-coated anodes, usually made by depositing mixed metal oxides onto titanium substrates, are an alternative to silicon-iron and graphite anodes. The ceramic anode makes CP available at one-half the life cycle cost of previous technologies and in a size reduction that permits installation in areas previously too small (Ref 13). One ampere of current supplied to the ceramic anode will stop corrosion on 46 m^2 (500 ft^2) of uncoated steel; that is, the consumption rate of conducting ceramic materials such as mixed metal oxides is 500 times less than the silicon-iron and graphite anodes. This has resulted in a smaller anode, weighing 50 times less, with the same life span and performance.

Advanced (Corrosion-Resistant) Materials Selection and Design. Industrial practice on the economical and safe use of existing materials changes with development of new materials and their application in different environments.

Coating degradation and corrosion can occur on steel vent pipes where a buried gas line

crosses under a roadway. Conventional practice is to use steel casings to prevent natural gas distribution lines from excessive traffic loads. Viable alternatives include the use of plastic vent pipes for this application, which is being field tested as part of a technology demonstration at an Army installation. If the demonstration project is successful, plastic vent pipes can then be used nationwide at a significant cost savings.

Other advanced material applications include the use of stainless steels and aluminum where coated carbon steel had been used in the past, as well as widespread use of composite materials as substitutes for steel where structural loading requirements can be met.

Water Treatment. Many military installations transport steam over long distances and use the steam in applications where toxic corrosion inhibitors cannot be used. The conventional civilian practice of using neutralizing amines is precluded in many of these applications. The Army is evaluating the use of "green" corrosion inhibitors such as othoxalated soya amines for corrosion control on condensate systems. Successful demonstration of these inhibitors will reduce the "CO₂ channeling" corrosion shown in Fig. 7. Automated monitoring of steam and condensate chemistry is expected to reduce the incidence of this type of corrosion (Ref 6, p 48).

Inspection and Monitoring. Nondestructive analysis of equipment condition is a priority with many DoD installations. Figure 14 shows where a clay sewer line on a military installation was breached during the horizontal insertion of a plastic gas distribution line. Discovery of five breaches of the sewer lines led the installation to question whether damage to other buried utilities had gone undetected. A remote camera was utilized to inspect more than 6000 m (20,000 ft) of buried sewer lines in only four weeks.

The inspections revealed no additional breaches of the sewer line due to gas pipeline penetration. However, the inspection did result in the identification of a blockage in one of the sewer lines and allowed maintenance personnel

Fig. 12 Deluge tank (for fire-suppression system) with test patches overcoat applied to lower half of exterior surface. Later, the entire tank was overcoated with a moisture-cure polyurethane system

Fig. 13 Rectifier with remote monitoring system (RMU) for use as part of an elevated water tower cathodic protection system for water side corrosion protection.

Fig. 14 Clay sewer line breached as a new gas distribution line was laid, due to lack of knowledge of where the sewer lines were located. A remote camera inserted into the sewer lines was later utilized to ascertain that no additional breaches had occurred.

to excavate and repair only the affected section of that pipeline. This saved an estimated 8 man-years in labor cost and completed the inspection in one-third of the time it would have taken if maintenance personnel had to excavate the entire area affecting the 400 housing units.

Remote inspection technologies, such as the sewer inspection camera system provide rapid assessment of the status of pipelines and eliminate extensive digging to determine locations where leaks or blockages are believed to exist. These systems can also be used for preventive maintenance purposes, for example, to determine if the pipe is beginning to corrode, or areas where the pipe wall thickness is reduced, so that corrective action must be taken.

Leak Detection. Corrosion of pipes often results in leaks. Leaks under pipe insulation can often result in additional corrosion. Acoustic emission leak detection technology has been developed to accurately locate and estimate the size of leaks in metallic water and fuel pipes. The technology operates at 15,000 Hz and, using coincidence detection, is capable of detecting leaks as small as 0.4 L/h (0.1 gal/h). Three acoustic sensors, with a minimum of two sensors bracketing the leak, are required for leak location. The sensors may be up to 600 m (2000 ft) apart. Implementation of this technique takes only about 1 h to investigate 1.6 km (1 mile) of pipeline. Acoustic leak detection technology pinpoints leaks for a small fraction of the cost of excavation normally used to locate the leaks. Drawbacks of this technology are: (a) it requires cables to connect the instrument to the sensors, and (b) it does not work as well in plastic pipes because of high attenuation, or in steam lines because of inherent noise.

Below-Grade Moisture Mitigation. Below-ground concrete facilities, such as basements and elevator shafts may sustain structural damage due to chronic water seepage through the walls. Electro-osmotic pulse (EOP) technology offers an alternative to the trench-and-drain approach by mitigating water-related problems from the interior of affected areas without the cost of excavation. The EOP method uses pulses of electricity to reverse the flow of water seepage, actually causing moisture to flow out of the basement walls, away from the building. Prior to application of the EOP system, major sources of active water were addressed by locating and repairing cracks with epoxy injection and/or hydraulic cement. Once active sources of intrusion are repaired, the system is installed to prevent the water from reaching the repair joint. The EOP system is installed by inserting anodes (positive electrodes) into the concrete wall or floor on the inside of the structure and by placing cathodes (negative electrodes) in the soil directly outside the structure. The power supply typically consumes 30 W of power for every 9 m² (100 ft²) treated. The EOP system is relatively easy to install compared to conventional waterproofing methods and costs about 40% less per linear foot of wall treated than traditional methods (Ref 6, p 48–50).

Conclusions

In summary, many corrosion problems associated with military installations are similar to those encountered in civilian installations. Military installations provide support for extensive training and preparedness for battle, and military culture revolves around execution of specific military missions. Corrosion of military facilities components and utilities, therefore, may be more likely to occur than in the civilian sector, since the military budgets provide more funds for maintenance of weapons and field equipment or training than for preventive maintenance for facilities. Also, installation maintenance personnel are frequently unaware of emerging technologies and best practices that could significantly reduce corrosion problems. Efforts associated with corrosion control must emphasize understanding of available corrosion-control techniques used in other industries and applying corrosion-monitoring techniques to critical military facilities.

Ground Vehicle Corrosion

I. Carl Handsy, U.S. Army Tank-Automotive & Armaments Command
John Repp, Corpro/Ocean City Research Corporation

THE U.S. ARMY has one of the largest tactical ground vehicle fleets in the world. These systems are continually being updated with the latest in weaponry, electronics, and fighting hardware. However, the basic structure of the vehicles remains largely unchanged. Most of this materiel was designed with automotive technologies for corrosion protection that were used in the 1970s and 1980s. These technologies cannot provide the level of corrosion protection necessary to maintain a vehicle for desired life of 15 to 25 years.

With a fleet of more than 120,000 vehicles for "High Mobility Multi-Wheeled Vehicles" (HMMWV or Humvees) alone, it is easy to see why deterioration due to corrosion is a major issue. As the average age of vehicles in the fleet is more than 17.9 years (Ref 1), which is 5 to 10 years longer than current commercial automotive standard warranties for corrosion, there is need for improved corrosion control to maintain a continually aging fleet.

An overall discussion of the Army's current position on corrosion control for wheeled tactical vehicles is presented here and includes:

- Army requirement for corrosion control
- Testing to meet the requirement
- Improving supplemental corrosion protection, the use of corrosion-inhibitive compounds, maintenance procedures, and design considering corrosion

Background

Wheeled tactical vehicles first saw widespread use after World War I, following some initial limited use by the Marine Corps. At the time, the vehicles were manufactured using the same techniques and production lines as commercial automobiles. Today (2006), military vehicles are created with unique requirements, specifications, coatings, and equipment that are not common to commercial vehicles.

Army vehicles are developed and manufactured by contractors who specialize in making that specific item. Due to the unique requirements on these vehicles, hand assembly is needed along with automatic processes. The manufacturers do not always have large assem-

bly plants like those of the U.S. automakers, and this sometimes limits the state-of-the-art technology that can be incorporated, such as hot-dip galvanizing, electrodeposition coatings, and other technologies that the automotive industry uses.

However, such technologies can often be found at subvendors, so leveraging their abilities allows manufacturers of wheeled tactical vehicles to improve the product without investment in costly infrastructure.

Requirements for Corrosion Control

The Army's requirements for corrosion control are based on protecting its materiel from deterioration due to operation under normal conditions. For ground vehicles, these requirements are often based on corrosion-control technologies developed by the commercial automotive industry. However, the tactical environment in which Army vehicles must operate is more severe, and so more robust technologies and more stringent requirements may be required. This is the case for vehicles deployed in Southwest Asia. The soil was an ancient sea bed and is full of salts and other minerals that are extremely hostile to coatings and metals. The weather extremes of high winds, abrasive sand, and temperatures ranging from daytime 53 °C (128 °F) to 15 °C (60 °F) at night play havoc on all equipment.

In addition to corrosion-control requirements for coatings, observability and chemical agent resistance are of paramount concern. To prevent detection by infrared (IR) and other scanners and to allow for decontamination after chemical agent exposure, the Army has developed a chemical agent resistant coating (CARC) system. This unique coating formulation reduces the IR signature of a vehicle, provides a dull flat finish, and can be cleaned using a highly basic decontamination solution. It is required on any Army tactical system, and it must be compatible with the corrosion-control methods.

In the past, corrosion control was not a primary concern as the tactical vehicle life expectancy was relatively short. However, for some current vehicles the life can be greater than 25 years. As such, better corrosion control

is essential to producing an asset that can last for the specified life. The U.S. Army Tank-automotive and Armaments Command (TACOM) defines the corrosion prevention and control requirements in the procurement document.

Procurement Document

The requirements from a procurement document are summarized.

Corrosion Control Performance. The minimum service life in years of the vehicle, subsystem, or component is stated, and the operating conditions are given (high humidity, salt spray, gravel impingement, temperature range). The type and amount of maintenance to be given is stipulated.

A method of evaluating corrosion is given. The allowable level of corrosion is 0.1% of the surface (rust grade 8 per ASTM D 610, "Evaluating Degree of Rusting on Painted Steel Surfaces"). Further, a U.S. Army Corrosion Rating System is cited. There shall be no effect on form, fit, or function of any component due to corrosion.

Verification of Corrosion Control. The entire vehicle shall be evaluated for corrosion control by the accelerated corrosion test (ACT). The specified number of cycles that represents the vehicle service life is specified in the contract. For less than complete vehicles, the cyclic corrosion test per GM 9540P or equivalent such as the SAE J2334 shall be performed on the actual component for the number of cycles representing the service life (e.g., 160 cycles for the 20 year period of performance). All test panels and component parts shall be scribed per ASTM D 3359 prior to testing to validate performance of the paint or any other coatings. After completion of the test, the scribed area shall be scraped with a metal putty knife or equivalent to determine the extent of any coating undercutting/loss of adhesion of any coating and/or treatment. Alternative validation test methods must be approved by the government prior to fielding or manufacturing.

The pass/fail criteria for the ACT test and other tests is clearly defined. Any loss of form,

fit, or function shall be considered a corrosion failure and requires the same type of corrective action during or after the ACT as any other failure occurring during or after the initial production test. Loss of coating adhesion or corrosion emanating from the scribe shall be limited to 3 mm maximum at any point at the scribe. There shall be no blistering of the coating film in excess of 5 blisters in any 24 square inch area. The maximum blister size is 1 mm. There shall be no more than 0.1% surface corrosion (ASTM D 610, rust grade 8) on any component part (exclusive of the scribe). In addition, there shall be no loss of original base metal thickness greater than 5% or 0.010 in., whichever is less. Expendable items (identified as exempted parts prior to the test) shall retain their function for their intended service life and are not subject to these criteria.

Notes of Guidance and Caution. The procurement document provides assistance to the vendor, such as:

- Corrosion control can be achieved by a combination of design features (as in TACOM Design Guidelines for Prevention of Corrosion in Combat and Tactical Vehicles, March 1988) or any automotive corrosion design guide such as SAE J447, material selection (e.g., composites, corrosion-resistant metal, galvanized steel), organic or inorganic coatings (e.g., zinc phosphate pretreatment, corrosion-resistant plating, E-coat, powder coating) and production techniques (e.g., coil coating, process controls, welding, inspection, and documentation).
- Corrosion protection for low-carbon sheet steel can be achieved by hot-dip galvanizing in accordance with ASTM A 123, or electro-galvanized 0.75 mil minimum thickness per ASTM B 633 (or minimum coating thickness of 0.75 mil on pregalvanized sheet 0.063 in. or less), with zinc phosphate pretreatment, epoxy prime preferably E-coat primer and CARC top coat. Alternate designs may be evaluated by comparison to a galvanized sample (as described previously) using ASTM D 522 Mandrel Bend Test and Accelerated Corrosion Test GM 9540P and gravelometer testing. Failure constitutes a defect such as extensive corrosion at scribe, chipping of coatings, loss of adhesion, or significant penetration of base material (per ASTM D 3359).
- Due to changes in climatic conditions and the development of newer materials and processes, all accelerated corrosion tests undergo a continuous adjustment to reflect these conditions. Therefore, modifications to the testing are to be expected over time. However, any changes need to be agreed upon with the government prior to testing.
- CARC coatings over steel is not expected to be sufficient corrosion protection to achieve 10 year service life. In marine environments such a system usually delivers only a 5 year performance.

The above requirements are capable of being met using already proven materials and processes for corrosion control (Ref 2). Using the processes and procedures already in use by commercial automotive manufacturers will help improve the corrosion resistance of military vehicles and make a design life of greater than 20 years achievable.

Testing Systems to Meet the Army's Needs

As required by the procurement contract, existing or new corrosion-control technologies used in a vehicle system need to be evaluated to determine their benefit. Accelerated corrosion test methods can demonstrate differences in performance of competing alternatives, identify areas requiring additional corrosion protection, and demonstrate the interaction between corrosion and operation of the vehicle.

Preproduction Testing. These initial tests are used to screen candidate materials to evaluate their inherent corrosion resistance. Most commonly, these are short-term aggressive tests performed in a laboratory corrosion chamber (see the article "Cabinet Testing" in Volume 13A). Traditionally, methods such as the ASTM B 117 salt spray (fog) test were used to compare relative performance, but they had very little if any relation to actual field use.

In the 1990s it was found that newer cyclic tests provide a better correlation to actual exposure environments. The GM9540P and SAE J2334 test methods are now commonly used to evaluate painted metals to determine relative corrosion resistance and select the best candidate system.

Cyclic corrosion tests are generically similar, although their exact makeup can vary. Corrosion specimens are exposed to a combination of corrosive electrolyte (salt-water solution), high temperature, high relative humidity (RH), and ambient conditions (nominally 70 °F, or 20 °C, <50% RH). These events are used to introduce corrosive species (e.g., chloride ions) to the samples, create conditions that accelerate corrosion (increase time of wetness, TOW), and "bake" the salts onto the specimens so they can be activated during TOW. Using combinations of these events over a period of time can accelerate levels of corrosion to represent years of exposure in a matter of weeks or months. Additionally, gravel impingement using a gravelometer is used in conjunction during a test to simulate events found in actual vehicle usage (Ref 3–5).

Prototype Testing. As major subsystems or complete vehicles are assembled into prototypes, more detailed evaluations can occur. These evaluations are used to determine if interactions exist between any of the components of these assemblies and if their normal operation is affected by corrosion. Prototype testing is performed by combining durability and corrosion

inputs. For smaller subsystems, this can include periodic exercising of components during accelerated testing. For larger systems and vehicles, testing is performed using proving-ground-type accelerated corrosion tests (road tests).

A road test is a combination of driving mileage and corrosion inputs used to simulate the expected vehicle mission profile (Ref 6). A vehicle is run through road courses representative of various terrains (paved roads, gravel roads, cobblestone streets, cross-country trails) that the vehicle is designed to negotiate. Inter-mixed with these conditions are corrosion events to apply corrosive contaminants (electrolytes) to the vehicle and TOW. Operating this type of test exposes the vehicle to mechanical and corrosion stresses. This combination of tests can identify deficiencies in corrosion-control methods, which can then be remedied before large-scale production.

Analysis of Test Results. The nature of accelerated corrosion testing is such that a failure in the test increases the likelihood of observing the same failure in the field; however, *a lack of failure in the test does not mean a failure will not occur in the field*. This is the nature of accelerated testing, where the time for failures to occur is accelerated and not all failure mechanisms are accelerated at the same rate. This is why comparative testing is performed early in vehicle development, and road testing is used once all material choices have been made to identify any interactions between final assemblies.

Benefits. The results of accelerated corrosion tests are used as feedback to vehicle designers. These results can be used to improve the design of a vehicle, to identify other materials for certain systems, to improve maintenance requirements, or in cost-benefit analyses to identify trade-offs and value of adding additional corrosion protection. While it is often impractical to expect a tactical vehicle to last the desired 20+ years of service with no maintenance, accelerated tests can benchmark the relative life of specific systems and highlight maintenance activities that should be performed. This is used to develop the best possible system and to reduce life-cycle costs (LCC) to optimize service and performance.

Supplemental Corrosion Protection

Supplemental corrosion protection improves the corrosion resistance of a material. These methods can include:

- Galvanizing of steel
- Plating of metals
- Sacrificial coatings
- Organic coatings

Each of these can be used as part of a system to reduce corrosion. While individually each does increase service life, combinations of these are needed to reach the >20 year design life

presently being requested of new wheeled tactical vehicles.

For example, a steel body using double-sided galvanized sheet steel and a CARC system will be protected more effectively than CARC or galvanizing alone. Using the above with a good pretreatment such as zinc phosphate, a high-performing primer such as E-Coat, followed by the top coat a 20+ year service life is economically achievable. The CARC system provides the first line of defense against contaminants. Without this coating, corrosion of the galvanized steel would begin immediately at voids. Conversely, if only the coating was used, once contaminants penetrated the CARC corrosion of steel substrate would begin immediately.

Corrosion-Inhibitor Compounds. For existing equipment, there may be components or locations (crevices, recesses, blind holes) that are vulnerable to corrosion attack. The entire vehicle may need extra protection during shipping or storage. Temporary inhibitive compounds may be used to reduce corrosive attack.

Corrosion-inhibitor compounds are most commonly liquid aerosols sprayed onto vehicles. Other forms include vapor-phase inhibitors, greases, and waxes. Most of these products are similar to other maintenance fluids used in motor pools and, as such, their use is implemented as maintenance procedures or in specialized service locations. However, similar to other lubricants and fluids, they need to be handled and applied with care. Some materials have been found to be detrimental to rubbers and plastics with prolonged exposure. Overspray can also be of concern, as this can attract dirt and contaminants and increase maintenance time by necessitating postapplication washing.

The U.S. Marine Corps have published guidance on the use of inhibitors with ground vehicles (Ref 7). These documents stress application of products to specific components and locations. This has helped alleviate some of the potential incompatibility issues. For example, certain inhibitors may reduce corrosion on one type of metal, but accelerate attack on others.

Improved Maintenance Procedures

Maintenance procedures can also be used to combat corrosion. More frequent lubrication, application of inhibitors, and repainting can reduce corrosion damage. Although these procedures do have benefits, excessive maintenance can be both time and readiness prohibitive. With steadily decreasing operating budgets and a need to have vehicles ready-to-go, continual maintenance is not practical. Often a compromise between maintenance and corrosion control needs to be developed and realistic maintenance goals established.

While maintenance can be used to reduce corrosion, it should not be relied upon as the major corrosion-control method. Emphasis

should be placed on less labor-intensive methods.

Considerations for Corrosion in Design

Considerations for corrosion control during design of a vehicle goes beyond choosing proper base metals and coatings. It includes the geometry and manufacturing methods used to construct a vehicle. These methods are described in TACOM and Society of Automotive Engineers (SAE) guidance documents (Ref 8–10).

These documents stress using good construction practices and creating geometries that minimize water entrapment areas or promote drainage of those areas. Design of body panels and components should also minimize the use of sharp corners and edges, which reduce paint adhesion. Adhesives and seam sealants should be used along with continuous welds for joining to eliminate crevices and water seepage locations.

Conclusions

As new military vehicles are being produced and acquired, corrosion control is becoming a major component of the acquisition strategy. Requirements such as those discussed in this article are being used to improve the corrosion resistance of vehicles. Placing the focus on performance instead of materials allows manufacturers to select corrosion-control solutions that best work within their operations, yet provide the level of protection required. By looking to proven technologies already in use by commercial manufacturers, original equipment manufacturers can leverage this knowledge and improve their end product.

The Army has embraced accelerated corrosion test methods and evaluation techniques for tactical vehicles. These methods permit the demonstration of effective design choices. It provides the ability to evaluate new corrosion-control technologies as they become commercially viable for use on military vehicles.

Armament Corrosion

Nicholas Warchol, U.S. Army ARDEC

ARMAMENT SYSTEMS comprise guns and ammunition ranging from the M-16 machine gun and ammunition (5.56 mm) to the 155 mm mortar rounds and M198 howitzers that fire the rounds. This includes weapon systems found on tanks and other mobile units, so the number of systems is large.

Armament systems, must meet specified requirements, including functionality, environmental, time, and cost requirements. Functional requirements are that the system performs its basic task, that includes the ability to fire a projectile, aim, and rotate. Another requirement is that there must be visual and spectral camouflage. Spectral camouflage refers to the infrared profile of the system and its ability to blend into the surrounding environment so the system is invisible to infrared-sighting equipment. This provides an extra level of tactical protection for the soldiers. The system must also be corrosion resistant and chemical-agent resistant. Chemical-agent resistance is the ability of the system to be decontaminated if it were to come in contact with chemical agents. These requirements are accomplished through the use of the chemical-agent resistant coating (CARC). It provides visual and spectral camouflage as well as corrosion and chemical-agent resistance. The CARC system consists of a primer and topcoat. The epoxy primer provides corrosion protection, while the urethane topcoat provides chemical-agent resistance and camouflage properties. Armament systems are exposed to some of the most severe environments on earth. Wars are not fought in a climate- and humidity-controlled environment. From arctic cold to desert heat the systems must be able to perform their function in all environments.

Overview of Design, In-Process, Storage, and In-Field Problems

Armaments corrosion problems must be looked at in four specific stages: design, in-process, storage, and in the field. To accurately understand the corrosion problems that are faced with today's (2006) armament systems, these aspects must be looked at individually and their effects analyzed over the useful life of the sys-

tem. Design considerations include geometry, material selection, assembly, pretreatment, coatings, and working and storage environments. In-process corrosion concerns include: processing locations, in-process storage of parts, time between processing steps, and quality control of each processing step. How, where, and how long the systems will be stored before they are fielded must be considered. Finally, analysis of the in-field corrosion of the finish product should include: physical environments; repair of corrosion-protective coatings, shipment concerns, general corrosion-protection maintenance, and appropriate fixes and procedures that can be implemented by soldiers in-field to stop continued corrosion of armament equipment.

There are common corrosion problems associated with each stage in the life of an armament system. The three most common types of corrosion associated with design are uniform, galvanic, and crevice corrosion. The most common form of corrosion during processing is uniform corrosion of parts being exposed to corrosive environments before the corrosion protection is in place. The most common form of corrosion for equipment in storage is uniform corrosion. This is again from parts being exposed to corrosive environments or being stored for periods longer than the protection systems are designed. The three most common forms of corrosion found on in-field systems are crevice, galvanic, and uniform. All types of corrosion are evident in all the stages; the process by which the most common armament corrosion is addressed within the military to ensure functional equipment reaches the field is discussed with applicable examples.

Design Considerations

From a design standpoint, one must be aware of the eight types of corrosion and consciously design the system for corrosion resistance. The functional goals of the system must be established in a set of requirements determining what is to be accomplished by this part, how the system will work, how long the system will need to function at a time, and what are the physical requirements on the system. In many cases,

with the designer's concern for the functional requirements of the system, corrosion is not a major consideration.

Material Selection. To adequately design a part to be corrosion resistant, the design engineer must first make good decisions in the materials selection process. When placing materials in a system, the design engineer must not only know the physical and mechanical properties of the materials, but also the susceptibility to corrosion of the material in specified environments of the system. For example, aluminum is often assumed to be a corrosion-resistant material, and for 1000-series aluminum this is generally correct. Different aluminum alloys have different corrosion susceptibilities. The design engineer must understand that if a material passivates when exposed to oxygen and it is placed in an environment that is absent of oxygen, then the corrosion resistance of the material is significantly reduced, if not completely destroyed.

Dissimilar Metals. Design engineers must also look at the interface of dissimilar metals within a system. Galvanic corrosion can destroy systems rapidly, especially in the case of a very large cathode in direct contact with a small anode. A galvanic series appropriate to the environment can be consulted, and all efforts should be made by the design engineer to use materials combinations that do not cause galvanic corrosion. See the compatibility chart based on MIL-F-14072D in the article "Corrosion in Microelectronics" (Table 6) in this Volume.

Design geometry can also play a large role in the susceptibility of a system to corrosion. Good practice is to eliminate crevices or seal crevices and joints. The design engineer must assume that water will get into parts or trap and pool on the surface of the system. The systems must be designed to drain water through holes, channels, or other devices. In pipes, the design engineer must prevent turbulent flow in joints in high-speed flow conditions. Bends, kinks, corners, and the internal features of the pipe all affect the flow and can increase erosion-corrosion within the system.

Coatings applied to the systems must also be researched and chosen depending on the specific requirements of the system. The previously mentioned CARC system is designed to be a 15 year coating that provides chemical-agent

resistance, spectral and visual camouflage, as well as corrosion protection. It is a two-part system that is applied over a zinc phosphate coating. The epoxy primer, 25 to 50 μm (1 to 2 mils) thick, provides corrosion protection. The urethane topcoat is applied 50 to 75 μm (2 to 3 mils) thick and provides the camouflage and chemical-agent resistance.

Examples of Design-Related Problems. An example of design affecting the corrosion resistance of an engineered system is the M198 howitzer. There is an anodized 7079-T6 aluminum alloy ring gear that connects the upper carriage and the gun tube to the lower carriage and the trails. The ring gear allows the gun tube to rotate and is fastened to the upper and lower carriage with mounting bolts. Figure 1 shows the results of a poor design on the system. The upper carriage of the ring gear has become completely disconnected from the lower carriage and the gun tube has fallen to the ground. There are multiple problems with the design of this system. First, the material selected, 7079-T6 aluminum, is susceptible to stress-corrosion cracking (SCC) in the transverse direction. For SCC to occur, a susceptible material, a specific corrodent, and a sustained tensile load are needed. 7079-T6 aluminum has a transverse SCC threshold of 55 MPa (8 ksi). The 13 mm ($1/2$ in.) and 16 mm ($5/8$ in.) mounting bolts used to secure the ring gear to the upper and lower carriage, when proper torque is applied, produce 110 and 172 MPa (16 and 25 ksi) sustained tensile loads, respectively, at the countersink. This load is sufficient to produce SCC if a corrodent is present, and for aluminum alloys, 50% relative humidity is sufficient. In this case, all three cri-

teria for SCC are present and the material experienced a large amount of SCC. Figure 2 shows SCC at the countersink of the ring gear.

A second design problem deals with the anodized coating of the ring gear. The anodized coating is applied to the aluminum to reduce the susceptibility of the material to corrosion. For the M198 howitzer, the seal used to finish the anodized coating was deleted on the drawing. Without the seal, the anodized coating does not protect the ring gear from pitting, and the ring gear surface experienced extreme pitting (Fig. 3). The pitting that occurred in the countersink provided initiation points for the SCC to propagate and accelerate the corrosion damage. Both the SCC and pitting could have been easily avoided. If 7075-T73 aluminum had been selected, SCC would have been avoided since 7075-T73 has a SCC threshold of 303 MPa (44 ksi). Pitting would have been prevented by simply requiring the seal to be placed on the anodized coating.

A third example of design affecting corrosion resistance is the copper rotating band found on 40 mm grenades. The copper bands are swaged onto the steel or aluminum grenade body. This creates a crevice beneath the rotating band as well as creates a dangerous galvanic couple between base metal and copper. It is also common to find galvanic corrosion of steel adjacent to the copper-rotating band as seen with the 105 mm cartridge (Fig. 4). Another problem is that machining lubricants can become trapped in the crevice between the body and the rotating band. This lubricant can then seep out of the crevice and react with the copper band causing discoloration (Fig. 5).

Fig. 1 Results of ring gear failure in the M198 howitzer. Source: Ref 1

In-Process Considerations

In-Process Monitoring. If a part is not properly monitored during processing, there is no way to accurately determine the reliability of the resulting system. In-process corrosion will depend on the type of process and its sensitivity to changes in process variables. Where and for how long will the parts be stored between processing steps? Do the unfinished parts need to be transported for further processing? These are all questions that must be considered in the quality assurance (QA) program. Quality assurance uses

a system of quality assurance representatives (QARs), who are government employees who travel to vendors' plants to monitor the actions of contractors and subcontractors to ensure compliance.

Adherence to Specifications and Standards. To monitor processing, the QARs must know how the quality of parts being produced is monitored, requirements for the part, how finishes are applied, and the tests used to verify these requirements. Specifications and standards are cited in purchasing documents that contractors and subcontractors must follow. These specifications and standards also define the engineering requirements. The goal of a specification or a standard is to establish critical criteria to ensure proper function of a part or system.

There are many cases of contractors certifying that the specifications were met while not stating which tests were performed. In military contracting, a contractor or subcontractor must perform three steps after the parts have been produced to ensure acceptance by the military inspector. First the parts must be tested and data must be collected. Secondly, the data are presented in a certified test report (CTR). The CTR lists the tests run and the test procedure, displays the data collected, and provides proof that the work meets the requirements. Once this document has been created, a second document, the certificate of conformance (COC), can be issued. A COC states that the contractor completed all the necessary tests on the produced parts and has fulfilled the other contractual obligations such as documentation and shipping requirements.

Conflicting Technical Data. A major problem for in-process corrosion control is the existence of conflicting technical data. For example, there may be a requirement on a drawing that a certain test is to be run, but the document also cites another drawing that says that the test is not required. In this case, the QAR cannot check the contractor for the requirement on the primary drawing because there are conflicting data. These conflicting requirements can be corrected for future contracts, but a new solicitation or a change to the contract would be required to fix the current contract, so the parts may be shipped as is. In armament corrosion, the person who suffers is the soldier who receives parts that do not function as they are supposed to or do not last as long as they are needed.

Examples of In-Process-Related Problems.

An example of an in-process corrosion problem is 155 mm M549A1 ammunition rounds that needed a complete repainting only 4 months after the initial painting. M549A1 is a steel projectile that is phosphated and then painted with enamel. The rounds were produced in California and then shipped to Iowa to be filled. The rounds that arrived in Iowa were rusted and required complete repainting. This was due to incomplete application of the phosphate pretreatment. The benefit of the phosphate coating is lost if complete and uniform coverage is not obtained. Without a properly applied pretreatment, the original paint coating was unable to protect the surface of the ammunition.

Another example of an in-process corrosion problem is the M119 howitzer firing platform. The firing platform was required to be 7075-T73

aluminum with chromate conversion pretreatment and painted using the CARC primer and topcoat system. After five years of service in Hawaii, the firing platforms failed due to exfoliation corrosion. It was determined that new platforms were required and again the T73 heat treatment was specified. The new platforms with this heat treatment failed after 2 years of service. Figure 6 shows the failed firing platform. Figure 7 is a close-up of the exfoliation corrosion on the firing platform. The T73 temper was designated because it is highly resistant to exfoliation. Then why did the parts exfoliate in only two years of service? They were not tested or documented during production to verify that the parts had in fact been treated to the T73 condition. To obtain a T73 temper, a part must first be placed in a T6 temper. If the parts are not adequately heated, they will not achieve the T73 state and will not be resistant to exfoliation corrosion. In this case, the parts and the temper recipe were never tested under ASTM B 209, "Standard Specification for Aluminum and Aluminum Alloy Sheet and Plate." Based on the premature failure of the supposed 7075-T73 parts, it is apparent the treatment was not sufficient. To verify the heat treatment of the platforms, tensile bars were cut from a failed platform and tested. The results indicated that the parts were in fact not in the T73 condition. If the parts had been properly monitored with the heat

Fig. 5 Grenade body showing discoloration of copper rotating bands resulting from exposure to trapped machining lubricant. Source: Ref 4

Fig. 6 Failed M119 firing platform. Source: Ref 5

Fig. 7 Firing platform exfoliation corrosion. Source: Ref 5

treatment plan recorded or the parts tested, the inadequate heat treatment would have been discovered and corrective action taken.

Storage Considerations

Storage Practices. The third stage that must be considered for armament corrosion is storage. In armament systems, parts can and do sit in storage for extended amounts of time. The goal of storage is to have systems on hand that can be deployed on short notice. In this case, the military must use processes to prevent degradation without affecting the readiness of the systems. In some cases equipment is stored in climate-controlled facilities. Other common practices include volatile corrosion inhibitor (VCI) packaging, rust-preventative oils, and hermetically sealed packaging. These systems are designed to preserve the integrity of the system and not reduce readiness. Despite best practices, the most common type of corrosion during storage is general corrosion, caused by failed or non-existent corrosion protection.

Examples of Storage-Related Problems. Military storage is not a perfect system, and in many cases, the storage is longer than the protection scheme life, or the packaging is compromised. If the packaging is compromised and goes unnoticed, the protection is completely lost. Loss of protection can be as simple as a tear in the packaging, or wrapping the items in VCI packaging designed to protect the system for 2 years, but storing them for 5 years. There have also been examples of oils used to preserve equipment that are capable of unzipping heat-sealed packages. One must also consider how the parts or systems will be stored. If a system is stored outdoors, will personnel be available to inspect and perform maintenance on the storage system and will readiness be affected?

An example of how storage can affect the readiness of equipment is again the M198 howitzer. Howitzers were stored outside in the elements, with individuals monitoring the systems to ensure their readiness. The howitzers were placed in the “ready” position, meaning that the trails were lifted off the ground so the howitzers were ready to be towed (Fig. 8). The problem is the howitzer was not designed to be stored in this position. Drain holes in the lower carriage were placed in the back by the trails to allow water to drain from the system. However, in the “ready” position water does not drain from the lower carriage. Thus water accumulated inside the carriage and caused corrosion damage. Adding holes in the front of the lower carriage so water could drain from the system while in the “ready” position corrected the problem.

In-Field Considerations

The final stage in the life of an engineered system is in-field or in-service. This is the place recognized as the cause for degradation and fail-

ure and provides the true test to parts, systems, and corrosion protection.

Preventive Maintenance and Cleaning. In armament systems, maintenance and cleaning must be performed to realize the useful life of systems. Common maintenance activities include cleaning, oiling, paint touchups, and parts replacement. The design engineer generates the required maintenance procedures. The goal is to create a maintenance system that anticipates problems and provides adequate guidance on how to prevent or repair them. For each part in the system there are cleaning and replacement requirements that lay out what must be done and when they should be completed. These requirements can be long and comprehensive. With maintenance crews seeing multiple systems, the sheer volume of manuals to be studied and reviewed before maintenance is performed is a daunting task. In this case, most crews develop a system of general practices for cleaning and

repairing parts. The other case is that the crews will be told to clean this system. The crew will then determine the best way to clean it. They could clean it by hand using solvents, then let it dry, and finally re-oil the equipment, or they could simply power-wash the equipment and then re-oil. The process of solvent cleaning and drying can take upwards of 4 h, while power-washing the parts and oiling with a water-displacing oil will take 5 min. It is easy to see which is done more often, and without guidance or properly reading the manuals the soldiers do not see the benefit associated with the other process. Figure 9 shows a soldier using a pressure washer to clean ammunition containers. The problem with this process is that the rubber seals on the storage containers are only watertight to 21 kPa (3 psi), and the soldier is washing the containers at a pressure of 690 kPa (100 psi).

The real problem with this situation is that systems are often designed to require a large

Fig. 8 M198 howitzer in “ready” position. Source: Ref 5

(2) Suspension							GAA	
(3) Cam assembly							GAA	
(2) Traveling lock clamp assembly						CLP		

(a) Numbers in parenthesis in the left-hand column represent the number of corroded parts per assembly. (b) Planned maintenance checks and services (PMCS) requirements: B, before operation; D, during operation; A, after operation; W, weekly; M, monthly. (c) Lubrication requirements: D, daily; W, weekly; Q, quarterly. (d) Lubrication subentries: CLP, cleaner, lubricant, and preservative; GAA, grease, automotive, and artillery; OHT, hydraulic fluid, petroleum base; BFS, brake fluid, silicon; WTR, wide temperature range. Source: Ref 7

amount of maintenance. There is monthly, weekly, and in some cases daily maintenance required to keep systems functioning. This process removes the design engineer from responsibility if the system fails, because it is not the designer's fault that the maintenance was not completed. If a part is designed to require little or no maintenance and the part fails, then the design is faulty. Table 1 shows the maintenance schedule for the M119 howitzer. It is apparent the M119 requires a large amount of maintenance to keep parts in working order. For example, the recuperator recoil mechanism has planned maintenance checks and services before, during, and after use. There are also weekly and monthly checks. Hydraulic fluid and cleaner, lubricant, and preservative (CLP) must be applied daily. The M119 howitzer has daily maintenance requirements for 9 of the 19 subassemblies in the system. For armament corrosion, this raises the question whether it is realistic to assume soldiers will be able to complete required maintenance for equipment in a war-fighting condition. If parts will not receive the maintenance, then they have simply been designed to fail.

Conclusions

Of the forms of corrosion, the ones that are experienced most in armament systems are general or uniform corrosion, galvanic corrosion, and crevice corrosion. These types of corrosion account for a large portion of the corrosion problems found in armament systems, but are not the only causes of corrosion. In this case, everyone involved with an armament sys-

tem needs to be aware of the types of corrosion, their causes, and steps that can be taken to prevent degradation. If everyone involved in a system is consciously trying to avoid problems associated with these types of corrosion then the readiness of equipment will be drastically increased and the total cost to the government associated with these systems will be reduced.

High-Temperature Corrosion in Military Systems

David A. Shifler, Naval Surface Warfare Center, Carderock Division

HIGH-TEMPERATURE CORROSION AND OXIDATION occur in various military applications. Aircraft, ships, vehicles, weapon systems, and land-based facilities require power that may be supplied by boilers, diesel engines, gas turbines, or any combination of the three power sources. High-temperature exposure of materials occurs in many applications such as power plants (coal, oil, natural gas, and nuclear), land-based gas turbine and diesel engines, gas turbine engines for aircraft, marine gas turbine engines for shipboard use, waste incineration, high-temperature fuel cells, and missile components. The service performances of boilers, diesels, and turbines can be affected by exposure to numerous environments and are affected by temperature, alloy or protective coating composition, time, and gas composition. Materials degradation can lead to problems that often bring about unscheduled outages resulting in loss of reliability, loss of readiness, decreased safety, and increased maintenance costs.

Predicting corrosion of metals and alloys or coated alloys is often difficult because of operational demands placed on a given power system, the range of the composition of corrosive gaseous or molten environments, and the variety of materials that may be used in a given power system. Moreover, corrosion prediction is further complicated because materials often degrade in a high-temperature environment of a given application by more than a single corrosion mechanism. High-temperature corrosion in boilers, diesel engines, gas turbines, and waste incinerators are discussed in this article.

High-Temperature Corrosion and Degradation Processes

There are a number of corrosion and degradation processes that may occur in boiler, diesel engines, gas turbine engines, and incinerators. The degree of degradation is dependent on the material being exposed and the specific environment and other conditions to which the material is exposed. High-temperature corrosion/degradation of materials may occur

through a number of potential processes described in the article "High-Temperature Gaseous Corrosion Testing" in Volume 13A, of the *ASM Handbook* (Ref 1), either singly and/or in some combination with one another:

- Oxidation
- Carburization and metal dusting
- Sulfidation
- Hot corrosion
- Chloridation and other halogenization reactions
- Hydrogen damage, hydrogen embrittlement
- Molten salts
- Aging reactions such as sensitization
- Creep
- Erosion/corrosion
- Environmental cracking (stress-corrosion cracking and corrosion fatigue)

Boilers

Boilers may be used to supply heating and cooling, main power, or auxiliary power at a number of land-based military installations. Marine boilers may be used to heat water and to produce steam to generate main power, auxiliary power, or industrial services.

When the first boiler was installed in 1875, boilers were used to supply power for primary propulsion for U.S. naval ships. The need for higher power, lower weight, and smaller footprint designs for ships forced boiler advances that were later adopted for current stationary designs (Ref 2). The primary propulsion systems of most ships have progressed to diesels, gas turbines, and nuclear power systems, but boilers still play a vital role in select ship systems. Shipboard space is critical, and marine boilers must fit within a minimum engine room space and be accessible for operation, inspection, and maintenance. Marine boilers must be rugged to operate and absorb vibration and forces resulting from rolling and pitching in rough seas. Boiler design needs to be conservative so that continuous operation is ensured over a long period of time without extensive maintenance.

There are two types of boilers: fire tube and water tube boilers. In fire tube boilers, the hot gases are on the inside of the tubes and the water is on the outside, and the boiler is usually used without superheat. In water tube boilers, the water is on the inside of the tubes and the hot gases are on the outside. Only water tube boilers can be used in large installations. The conventional steam cycle used in larger water tube boilers is the Rankine cycle. The Rankine cycle consists of compression of liquid water by a boiler feed pump, heating to the saturation temperature in an economizer, evaporation in the furnace, expansion work in the steam turbine, and condensation of the exhaust steam in a condenser. Steam cycle efficiency can be improved by adding superheater tubes to heat the steam above saturation temperatures. Reheat cycles further improve boiler efficiency. For pressures below 22 MPa (3200 psia), a steam drum is required to provide a tank volume sufficient to separate water from steam. The separated water, together with boiler makeup feedwater from the economizer, is returned by unheated downcomer tubes. For natural circulation boiler design (boilers <20 MPa, or 2900 psia), the fluid temperature in the heated riser tubes remains constant. The driving force for natural circulation boilers is the difference in fluid density between the heated risers and the unheated downcomers with the steam drum at the top of the boiler unit (Ref 3).

There are several types of boilers used in land-based and sea-based military applications: integral-furnace naval boilers, auxiliary package boilers, and waste heat boilers (Ref 2). Boilers may be fired by using coal, special residual oil, or natural gas as the primary fuel. Discussion and diagrams of marine boilers can be found in several publications (Ref 2, 4). Steels, cast irons, stainless steels, and high-temperature alloys are used to construct various boiler components. Boiler construction materials conform to ASME International specifications (Ref 5, 6) or other pertinent specification bodies.

In all boiler tubes, adequate circulation must be provided to avoid critical heat flux or departure from nucleate boiling (DNB) when the rate

of bubble nucleation on the boiler tube surfaces exceeds the rate by which the bubbles are swept away. The overall volume of steam becomes too great, and DNB forms a continuous film of steam on the metal surface. The DNB depends on many variables, including pressure, heat flux, and fluid mass velocity.

Design defects, fabrication defects, improper operation, and improper maintenance are some of the common causes for boiler failures. Elevated-temperature and corrosion failures are common failure modes for boilers. Additionally, mechanical failures due to phenomena such as fatigue or wear occur as well. Some of the most common failure modes for boilers used for steam generating include overheating, fatigue or corrosion fatigue, fireside or waterside/steam-side corrosion, stress-corrosion cracking, and defective or improper materials.

The Electric Power Research Institute (EPRI) described 22 mechanisms, shown in Table 1, that are primarily responsible for boiler tube failures experienced in electric utility power generation boilers (Ref 7). The major failure categories are: (a) stress rupture, (b) waterside corrosion, (c) fireside corrosion, (d) erosion, (e) fatigue, and (f) lack of quality control. The classifications are arbitrary and based on visual characteristics of attack morphology. Reference 8 describes these failure modes.

Stress Rupture Failures in Boiler Environments. Stress and temperature influence the useful life of the tube steel. The strength of the boiler tube within the creep range decreases rapidly when the tube metal temperature increases. Creep entails a time-dependent deformation involving grain sliding and atom movement. When sufficient strain has developed at the grain boundaries, voids and microcracks develop. With continued operation at high temperatures, these voids and microcracks

will grow and coalesce to form larger and larger cracks until failure occurs. The creep rate will increase, and the projected time to rupture will decrease when the stress and/or the tube metal temperature increases. High-temperature creep generally results in a longitudinal, fish-mouthed, thick-lipped rupture that has progressed from overheating over a long period of time. High-temperature creep can develop from insufficient boiler coolant circulation, long-term elevated boiler gas temperatures, inadequate material properties, or as the result of long-term deposition. A thick, brittle magnetite layer near the failure indicates long-term overheating.

High-temperature creep failures can be controlled by restoring the boiler components to boiler design conditions or by upgrading the tube material (either with ferritic alloys containing more chromium or with austenitic stainless steels). Failure from overheating caused by internal flow restrictions or loss of heat-transfer capability can be eliminated by removal of internal scale, debris, or deposits through flushing or chemical cleaning.

Boiler tubes exposed to extremely high temperatures for a brief period—metal temperatures of 455 °C (850 °F) and often exceeding 730 °C (1350 °F)—also fail from overheating. The overheating may occur from a single event or a series of brief events. Short-term overheating, generally, is related to tube pluggage, insufficient coolant flow due to upset conditions, and/or overfiring or uneven firing patterns. Loss of coolant circulation may be caused by low drum water levels or by another failure located downstream in the same tube. Inadequate coolant circulation can result in DNB in horizontal or sloped tubes when steam bubbles forming on the hot tube surface interfere with the flow of water coolant to the surface. This restricts the flow of heat away from the tube. Normally, the short-term overheating failure will exhibit considerable tube deformation from bulging, metal elongation, and reduction of wall thickness. Normally, the rupture will be longitudinal, fish-mouthed, and thin-lipped. Often, the suddenness of the rupture bends the tube. Very rapid overheating may produce a thick-lipped failure. A metallurgical analysis can determine tube metal temperature at the moment of rupture. Heavy internal deposits often are absent from a short-term overheating failure.

Since short-term overheating failure is caused most often by boiler upsets, rectifying any abnormal conditions can eliminate these ruptures. If restricted coolant flow or plugged sections are responsible, the boiler should be inspected and cleaned. Boiler regions with high heat flux may be redesigned with ribbed or rifled tubing to alleviate film boiling. Boiler operation should be monitored to avoid rapid start-ups, excessive firing rates, low drum levels, and improper burner operation.

Waterside corrosion failures often occur due to contamination of boiler feedwater. Maintaining cleanliness of the boiler water is

critical for long-term, low-maintenance operation of boilers. The mineral and organic substances present in natural water supplies vary greatly in their relative proportions, but principally comprise carbonates, sulfates and chlorides of lime, magnesia and sodium, iron and aluminum salts, silicates, mineral and organic acids, and the gases oxygen and carbon dioxide. Scale is formed from the carbonates and sulfates of lime and magnesia and from the oxides of iron, aluminum, and silicon, and it will result in:

- Reduction in the boiler efficiency because of the decreased rate of heat transfer
- Overheating and burning of tubes resulting in tube failure

Scales are dangerous long before they reach this thickness. A very thin scale can cause tube failure due to overheating. Scale has about 2% of the thermal conductivity of steel. A scale thickness of about 1 mm (0.04 in.) can be sufficient to reduce the heat-transfer rate to a dangerous point; when the water inside the tube cannot receive and carry away the heat fast enough from the tube alloy to keep it below its transformation temperature, the tubes “burn out.”

Water and waterside chemistries are important in maintaining protection of internal tube surfaces, but they also can contribute to waterside corrosion problems such as caustic gouging, hydrogen damage, pitting, or dealloying. The change in pH can markedly affect the corrosion rate of steel by water. Upsets in water chemistry can affect the corrosion rate and the amount of deposition on the tube wall.

Caustic corrosion (also referred to as caustic gouging, caustic attack, or ductile gouging) results from deposition of feedwater corrosion products, in which sodium hydroxide can concentrate to high pH levels. The hydroxide solubilizes the protective magnetite layer and reacts directly with the iron (Ref 9, 10):

Sodium hydroxide can concentrate under porous deposits through a mechanism called wick boiling. Deposition occurs at the highest heat input areas and accumulates at flow disruptions such as downstream of backing rings, around tube bends, and in horizontal or inclined tube regions. Caustic corrosion results in irregular wall thinning or gouging. Failures develop after critical wall loss. During DNB conditions, boiler water solids will develop at the metal surface, usually at the interface between the bubbles and the water. Corrosive solids will precipitate at the edges of the blanket with corresponding wall loss. The metal under the DNB blanket is largely intact. A visual examination often can identify caustic gouging (Ref 9). Ultrasonic examination can detect regions where caustic gouging may occur. Metallurgical examination may or may not reveal an overheated microstructure in the region affected

Table 1 Electric Power Research Institute classification of boiler tube failure modes

Failure mode	Causal factor
Stress rupture	Short-term overheating High-temperature creep Dissimilar metal welds
Erosion	Fly ash Falling slag Sootblower Coal particle
Waterside corrosion	Caustic corrosion Hydrogen damage Pitting (localized corrosion) Stress-corrosion cracking
Fatigue	Vibration Thermal Corrosion
Fireside corrosion	Low-temperature Waterwall Coal ash Oil ash
Lack of quality control	Maintenance cleaning damage Chemical excursion damage Materials damage Welding defects

Source: Ref 7

by caustic gouging. Analysis of the bulk deposit by energy-dispersive spectroscopy (EDS) analysis and/or x-ray mapping can distinguish regions of high sodium content caused by caustic gouging.

Caustic corrosion may be reduced by minimizing the entry of deposit-forming materials into the boiler and by performing periodic chemical cleanings to remove waterside deposits. Monitoring the water chemistry to reduce the amount of available free sodium hydroxide, preventing in-leakage of alkaline-producing salts into condensers, preventing DNB, using ribbed tubing in susceptible areas, and eliminating welds with backing rings or joint irregularities can reduce or negate caustic gouging.

Hydrogen damage also results from fouled heat-transfer surfaces. There is some disagreement as to whether hydrogen damage can occur only under acidic conditions or whether it can happen under alkaline and acidic conditions as well. Hydrogen damage may occur from the generation of atomic hydrogen during rapid corrosion of the waterside tube surface, although it may occur with little or no apparent wall thinning. The atomic hydrogen diffuses into the tube steel, where it reacts with tube carbides (Fe_3C) to form gaseous methane (CH_4) at the grain boundaries. Large methane gas molecules concentrate at the grain boundaries. When methane gas pressures exceed the cohesive strength of the grains, a network of discontinuous, intergranular microcracks is produced. Often, a decarburized tube microstructure observed by metallographic examination is associated with hydrogen damage. The cracks grow and link together to cause a thick-wall failure. Hydrogen damage has been incorrectly referred to in the literature and in practice as hydrogen embrittlement; actually, the affected ferrite grains have not lost their ductility. However, because of the microcrack network, a bend test will indicate brittlelike conditions.

Hydrogen damage and caustic gouging are experienced at similar boiler locations and, usually, under heavy waterside deposits. Hydrogen damage from low-pH conditions may be distinguished from high-pH conditions by considering the boiler water chemistry. A low-pH condition can be created when the boiler is operated outside of normal recommended water chemistry parameter limits. This is caused by contamination such as: (a) condenser in-leakage (e.g., seawater or recirculating cooling water systems incorporating cooling towers), (b) residual contamination from chemical cleaning, and (c) the inadvertent release of acidic chemicals into the feedwater system. A mechanism for concentrating acid-producing salts (DNB, deposits, wateline evaporation) must be present to provide the low-pH condition. Low pH will dissolve the magnetite scale and may attack the underlying base metal through gouging (Ref 9, 11):

Proper control of the water chemistry and removal of waterside deposits may eliminate hydrogen damage when concentrating boiler solids occur. History and details of caustic embrittlement and hydrogen damage and embrittlement are discussed elsewhere (Ref 11).

Passive film breakdown is followed by the formation of a concentration cell. At the anode, the metal oxidizes, while at the much larger cathode surface surrounding the pit, oxygen or hydrogen is reduced. Pit propagation is autocatalytic. The rapid metal dissolution within the pit tends to produce an excess of positive charges within the cavity, resulting in migration of chlorides, sulfates, thiosulfates, or other anions into the pit cavity to maintain electroneutrality. Hydrolysis of metal salts ($\text{M}^+ \text{Cl}^- + \text{H}_2\text{O} = \text{MOH} + \text{H}^+ \text{Cl}^-$) forms an insoluble metal hydroxide and a free acid, which decreases the pH. Low pH results in rapid corrosion (Ref 9, 11).

Boiler steels pit in the presence of moisture and oxygen. This generally occurs when the boiler is not operational and has not been completely dried or protected by a nitrogen blanket during shutdown. Pitting attack from dissolved oxygen in pools of condensation has been found in reheater tubing. Pitting in the economizer section materializes during start-ups and low-load operations because of high oxygen levels. Oxygen pitting can be corrected if hydrazine-treated water and a proper nitrogen blanket are used during shutdown.

The propagation of crevice corrosion is similar to the propagation of pitting. The crevice-corrosion initiation stage differs from pitting initiation because the crevice is an artificial pit. The anodic reaction will predominate within the crevice after oxygen or hydrogen reduction diminishes; the oxygen or hydrogen reduction reaction predominates outside the crevice. Waterside deposits, silt, sand, and shells can be found on the tube surfaces producing such crevices. Underdeposit attack is usually uniform on steel, cast iron, and most copper alloys.

Intergranular corrosion occurs at or adjacent to grain boundaries with little corresponding corrosion of the grains. Intergranular corrosion can be caused by impurities at the grain boundaries or enrichment or depletion of one of the alloying elements in the grain-boundary area. Austenitic stainless steels such as type 304 become sensitized or susceptible to intergranular corrosion when heated in the range of 510 to 790 °C (950 to 1450 °F). In this temperature range, Cr_{23}C_6 precipitates form and deplete chromium from the area along the grain boundaries (below the level required to maintain stainless properties). The chromium-depleted area becomes a region of relatively poor corrosion resistance. Controlling intergranular corrosion of austenitic stainless steels occurs through: (a) employing high-temperature solution heat treatment, (b) adding elements (stabilizers) such as titanium, niobium, or tantalum that are stronger carbide formers than chromium, and (c) lowering the carbon content below 0.03%. Other

alloys such as aluminum, ferritic stainless steels, and bronzes are also affected by intergranular corrosion. A microscopic, metallographic examination and SEM/EDS can determine the degree of degradation. Several standard tests can evaluate the susceptibility of different alloys to intergranular corrosion.

In order to minimize corrosion associated with the watersides and steamsides of steam generators and other steam/water cycle components, a comprehensive chemistry program should be instituted. There are a wide variety of chemical treatment programs that are utilized for these systems depending on the materials of construction, operating temperatures, pressures, heat fluxes, contaminant levels, and purity criteria for components using the steam. Minimizing the transport of corrosion products to the steam generator is essential for corrosion control in the steam generator. Corrosion products from the feedwater deposit on steam generator tubes, inhibit cooling of tube surfaces, and provide an evaporative-type concentration mechanism of dissolved salts under boiler tube deposits. Therefore, the chemistry of water in contact with the tube surfaces is often much worse than in the bulk water. In general, the higher the pressure of the operating boiler, the more critical the control of water chemistry is for proper operation of the system.

Fireside corrosion failures are dependent on the type of fuel environment and the component metal temperature. The corrosiveness of the environment depends on the surface temperature and the condition of and/or the corrosive ingredients in the medium. External corrosion of steel piping can occur under wet fiberglass insulation at room temperature. Fiberglass contains soluble chlorides that can be leached out when the insulation becomes wet and can concentrate at the metal surface. This promotes corrosion.

Low-temperature or dew-point corrosion results from the condensation of sulfuric acid or other acidic flue gas vapors when the component temperature drops below the acid dew point or is operated below the acid dew point so that condensate will form a low-pH electrolyte on fly ash particles and produce acid smuts. Dew-point corrosion failures in boilers lead to stress rupture of the tube steel from loss of load-carrying material on the fireside surface. The external surface will be gouged or pitted. Sulfuric acid is formed when moisture reacts with sulfur trioxide. The acid dew point is related to the concentration of sulfur trioxide in the boiler flue gas (at 10 ppm SO_3 , the dew point is approximately 140 °C, or 280 °F). Dew-point corrosion can be corrected by the injection of enough magnesium oxide to neutralize the acid. Minimizing excess oxygen will reduce the formation of SO_3 . When SO_3 is maintained below 10 ppm, dew-point corrosion is often not a problem. Dew-point corrosion is thoroughly discussed in another source (Ref 12). The primary methods of control are: (a) keeping the metal at a temperature above the acid dew point, (b) specifying low-sulfur fuels, and (c) removing fireside deposition from

metal surface immediately after boiler shutdown using high-pressure water sprays followed by neutralizing lime solutions.

Corrosive constituents in fuel at appropriate metal temperatures may promote fireside corrosion in boiler tube steel. For coal, lignite, oil, or refuse, the corrosive ingredients can form liquids (liquid ash corrosion) that solubilize the oxide film on tubing and react with the underlying metal to reduce the tube wall thickness. This can occur in the combustion zone (e.g., waterwall tubes) or convection pass (e.g., superheaters). Technologies to reduce NO_x emissions from the boiler also result in more reducing conditions in the furnace, which greatly increases the potential for liquid ash corrosion. This has been alleviated by installing air ports along the walls to create an air blanket and installing stainless steel and high-alloy weld overlays.

Waterwall fireside corrosion may develop when incomplete fuel combustion causes a reducing condition because of insufficient oxygen. Incomplete combustion causes the release of volatile sulfur and chloride compounds, which causes sulfidation and accelerated metal loss. Poor combustion conditions and steady or intermittent flame impingement on the furnace walls may favor an environment that forms sodium and potassium pyrosulfates ($\text{Na}_2\text{S}_2\text{O}_7$ or $\text{K}_2\text{S}_2\text{O}_7$), which have melting points below 427°C (800°F). The presence of chlorides lowers the melting temperature of the combined molten salts and increases the corrosion rate of steel. Pyrosulfate formation due to sufficient presence of SO_3 and alkalis can cause significant corrosion and metal wastage at temperatures from 400 to 595°C (750 to 1100°F) (Ref 13).

Metal attack occurs along the crown of the tube and may extend uniformly across several tubes. Corroded areas are characterized by abnormally thick iron oxide and iron sulfide scales. Visual, microscopic, and SEM/EDS analyses may identify the corrodent. Verification of waterwall fireside corrosion involves analyzing the fuel, the completeness of combustion, and the evenness of heat transfer. Carbon contents in the ash greater than 3% are indicative of reducing and corrosive combustion conditions. The ratio of carbon monoxide to carbon dioxide may be indicative of whether oxidizing or reducing conditions are prevailing, but local condition may differ considerably from the bulk environment.

The reducing conditions tend to lower the melting temperature of any deposited slag, which also increases the solvation of the normal oxide scales. A stable gaseous sulfur compound under reducing conditions is hydrogen sulfide (H_2S). Under the reducing environment, iron sulfide is the expected corrosion product of iron reacting with pyrosulfates. Sulfur prints will show the sulfide in the corrosion products around the metal surface penetrations.

Operating factors that may improve combustion conditions are: (a) better coal grinding, (b) amended fuel distribution, (c) increased and re-distributed secondary air, and (d) supplemented

air into the boiler. However, this may provide only a marginal improvement. A complete furnace modification may be required. Pad welding may be economical for low levels of fireside corrosion, while coatings may provide short-term protection.

Coal ash corrosion results when a molten ash of complex alkali-iron trisulfates forms on the external surfaces of reheater and superheater tubes in the temperature range of 540 to 705°C (1000 to 1300°F). Liquid trisulfates solubilize the protective iron oxide scale and expose the base metal to oxygen, which produces more oxide and subsequent metal loss, according to a mechanism proposed by Reid (Ref 13):

Alkali sulfates, originating from the alkalis in the fuel ash and the sulfur oxides in the furnace atmosphere are deposited on the metal oxide layer setting up a temperature gradient. The alkali sulfates attract fuel ash. The temperature of the fuel ash increases to a point where sulfur trioxide is released by thermal dissociation sulfur compounds within the ash. The sulfur trioxide then migrates toward the cooler metal surface. Reaction of sulfur compounds with the metal oxide forms alkali metal sulfates and dissolves the protective alloy film. Reaction of the alkali metal trisulfates can reform iron oxide and iron sulfide. The iron sulfide will react with available oxygen to SO_2 and SO_3 . The net overall reaction is:

which accounts for the metal loss. The greatest metal loss creates flat sites at the interface between the fly-ash-covered half and the uncovered half (2 and 10 o'clock positions to the gas flow). Corrosive coal typically contains a significant amount of sulfur and sodium and/or potassium compounds.

Visually, ferritic steel will exhibit shallow grooves (referred to as alligating or elephant hide). A sulfur print will reveal the presence of sulfides at the metal/scale interface. Coal ash corrosion reduces the effective wall thickness, thereby increasing tube stress. This combined with temperatures within the creep range may cause premature creep stress ruptures because of coal ash corrosion.

Fireside corrosion can also occur in oil-fired boilers. As in coal combustion, SO_2 and SO_3 form in relative amounts depending primarily on the temperature. In excess air, vanadium forms vanadium pentoxide (V_2O_5) and sodium forms sodium monoxide (Na_2O). Together, V_2O_5 and Na_2O form a range of compounds that melt to

temperatures less than 540°C (1000°F). Oil ash corrosion is believed to be a catalytic oxidation of the material by reaction with V_2O_5 . Sodium oxide also reacts with sodium trioxide to form sodium sulfate, which together with V_2O_5 also forms a range of low-melting-point liquids with a minimum temperature around 540°C (1000°F) (Ref 13, 14). The temperature range precludes waterwall damage by this corrosion mechanism. Superheaters and reheaters may be prone to oil ash corrosion.

Several corrective options to reduce failure caused by fireside corrosion are: (a) employing thicker tubes of the same material, (b) shielding tubes with clamp-on protectors, (c) coating with thermal sprayed, corrosion-resistant materials, (d) purchase of fuels with low impurity levels (limit levels of sulfur, chloride, sodium, vanadium, etc.), (e) purification of fuels (e.g., coal washing), (f) blending coals to reduce corrosive ash constituents, (g) replacing tubes with higher-grade alloys or coextruded tubing, (h) adjustment of operating conditions (e.g., increasing percent excess air, percent solids in recovery boilers, etc.), (i) redesigning affected sections to modify heat transfer, (j) adding fuel additives such as calcium sulfate (CaSO_4) or magnesium sulfate (MgSO_4) to bind SO_3 to form a less corrosive form, and (k) modification of lay-up practices.

Environmental cracking failures can occur with a wide combination of metals and alloys, stress fields and mode, and in various specific environments. Environmental cracking is defined as the spontaneous, brittle fracture of a susceptible material (usually quite ductile itself) under tensile stress in a specific environment over a period of time. Stress-corrosion cracking (SCC), hydrogen damage, and corrosion fatigue are some of the forms of environmental cracking that can lead to failure.

Stress-corrosion cracking results from the conjoint, synergistic interaction of tensile stress and a specific corrodent for the given metal. The tensile stress may be either applied (such as caused by internal pressure) or residual (such as induced during forming processes, assembly, or welding). Stress-corrosion cracking involves the concentration of stress and/or the concentration of the specific corrodent at the fracture site. Fractures due to SCC may be oriented either longitudinally or circumferentially, but the fractures are always perpendicular to the stresses. In boiler systems, carbon steel is specifically sensitive to concentrated sodium hydroxide, stainless steel is sensitive to concentrated sodium hydroxide, chlorides, nitrates, sulfates, and polythionic acids, and some copper alloys are sensitive to ammonia and nitrites. Stress-corrosion cracking failures produce thick-walled fractures that may be intergranular, transgranular, or both. Branching is often associated with SCC. Normally, gross attack of the metal by the corrodent is not observed in SCC failures. Failures caused by SCC are difficult to see with the naked eye. Metallographic and chemical analyses are performed to identify the constituents in the alloy and the bulk corrosion products. Analytical

techniques such as EDS or Auger spectroscopy may be used to determine the source of the corrodent within the cracks. Magnetic particle or ultrasonic techniques can detect cracked regions in the boiler. A stress analysis can be conducted to determine if high applied or residual stresses are involved. A check of the background history of the failed component is particularly useful in assessing the contributing factors for this type of failure. Stress-corrosion cracking failures frequently have been experienced immediately after chemical cleanings and initial start-ups. Copper alloys, specifically brasses, are susceptible to SCC. Most steamside failures have occurred where high concentrations of ammonia and oxygen exist such as in the air-removal section of the condenser. Stress-corrosion cracking failures are found often at inlet or outlet ends where the tubes have been expanded into the tubesheet.

Stress-corrosion cracking may be reduced by either removing applied or residual stresses or avoiding concentrated corrodents. The reduction of corrodents by avoiding boiler upsets and in-leakage is generally the most effective means of diminishing or eliminating SCC. A change in tube metallurgy also may reduce SCC.

Boiler tube cyclic stresses are stresses periodically applied to boiler tubes that can reduce the expected life of the tube through the initiation and propagation of fatigue cracks. The environment within the boiler would suggest that corrodents would also interact with the tube to assist in this cracking process. The number of cycles required to produce cracking is dependent on the level of strain and the environment. Vibration and thermal fatigue failures describe the type of cyclic stresses involved in the initiation and propagation of these fractures.

Vibration fatigue cracks originate and propagate as a result of flow-induced vibration. This occurs where tubes are attached to drums, headers, walls, seals, or supports. Circumferential orientations are common to vibration fatigue cracks. Crack-initiation sites generally occur on the fireside (external) tube portions. Dye penetrant or magnetic particle techniques can detect crack sites. Metallographic examination can confirm fatigue cracking, which is often

transgranular. Vibration restraints can be installed to eliminate gas-flow-induced vibration and vibration fatigue cracking.

Thermal fatigue cracks develop from excessive strains induced by rapid cycling and sudden fluid temperature changes in contact with the tube metal across the tube wall thickness. This can be caused by rapid boiler start-ups above proper operational limits. Water quenching by spraying from condensate in the soot-blowing medium and from the bottom ash hoppers also can induce thermal fatigue cracks. Sudden cooling of tube surfaces causes high tensile stresses because cooled surface metal tends to contract; however, this metal becomes restricted by the hotter metal below the surface. Procedures that can reduce these sudden cyclic temperature gradients will diminish or eliminate thermal fatigue cracking.

The combined effects of a corrosive environment and cyclic stresses of sufficient magnitude cause corrosion fatigue failures. Corrosion fatigue cracks may develop at stress concentration sites (stress risers) such as pits, notches, or other surface irregularities. Corrosion fatigue is commonly associated with rigid restraints or attachments. Corrosion fatigue cracking most frequently occurs in boilers that operate cyclically. The fracture surface of a corrosion fatigue crack will be thick-edged and perpendicular to the maximum tensile stress. Multiple parallel cracks are usually present at the metal surface near the failure. Microscopic examination will detect straight, unbranched cracks. The cracks often will be wedge-shaped and filled with oxide. The oxide serves to prevent the crack from closing and intensifies the stresses at the crack tip during tensile cycles, thereby assisting in the crack growth.

Corrosion fatigue cracking can be reduced or eliminated by: (a) controlling cyclic tensile stresses (reducing or avoiding cyclic boiler operation or extending start-up and shutdown times), (b) redesigning tube restraints and attachments where differential expansion could occur, (c) controlling water chemistry to reduce the formation of stress risers such as pits, and (d) removing residual stresses by heat treatment, if possible. Some further discussions on environ-

mental cracking and corrosion fatigue can be found in other sources (Ref 15, 16).

Case History: Boiler Tube Failure (Ref 17).

The roof tube section from a land-based boiler at a military base failed. Figure 1 shows that the tube failure consisted of a 25 mm (1 in.) longitudinal split along the hot side. This split coincided with local bulging of the tube at the hot side crown. The tube sample was cut along the longitudinal, membrane axis. A side view of the respective waterside deposits (Fig. 2) indicated that the hot deposit was 25 mm (1 in.) thick in some places along the sample, while the cold side deposits were 0.13 to 0.51 mm (0.005 to 0.020 in.) thick. The roof tube was low-alloy carbon steel, which conformed to ASME SA 192 or SA 210 chemical specifications. The oxidation limit and maximum allowable temperature for these carbon steels is 455 °C (850 °F).

A view of the cold side microstructure (180° and opposite from the failure) by SEM as shown in Fig. 3 attests to the lamellar nature of the pearlite colonies in the ferrite matrix. The waterside deposit in the vicinity of the failure exhibited several distinct layers of oxide (Fig. 4). There was also heavy oxidation and corrosion of the waterside surface. The deposit shown in this micrograph is 0.61 to 0.71 mm (0.024 to 0.028 in.) thick. Some of the layers are quite dense while others are very porous. One layer exhibits a dispersion of copper metal particles while still another layer revealed needlelike, fibrous oxides.

In Fig. 5, the tube microstructure near the failure (~13 mm, or 0.5 in., away) displayed complete spheroidization of the carbides from overheating. Voids developed at grain boundaries, particularly at three-grain junctions; these voids tend to be oriented perpendicular to the tube surface. The formation of these voids is due to long-term overheating and creep rupture. Some of the voids have grown and coalesced into larger voids and incipient microcracks; some of the largest voids have formed surface oxides. There is slight elongation of the grains as a result of tube swelling and expansion. The micrograph in Fig. 6 is a higher-magnification view that clearly shows that the carbides at former pearlite colonies have fully spheroidized. Some of these

Fig. 1 Roof tube "as received." Narrow 25 mm (1 in.) long failure is along the hot side crown. See also Fig. 2 through 6.

Fig. 2 Side view of tube sample reveals that hot side deposits are as much as 25 mm (1.0 in.) thick. Relatively little deposition was present on the cold side

carbides have dispersed into the grains. Other random carbides are present along the grain boundaries; voids have formed at some of these grain-boundary sites. Void formation and propagation occurred in a direction perpendicular to the hoop stress.

The waterside deposit was extremely heavy, $>1100 \text{ mg/cm}^2$ (1000 g/ft^3) and unusual for a roof tube from a low-pressure boiler. The presence of high levels of copper in the tube deposit reportedly from the present, all-ferrous boiler system and the lack of any apparent contribution from the boiler water source tend to suggest that the deposits had formed long ago when copper alloys were used in the condenser or feedwater heater. The presence of the heavy deposits on the roof tube sample interfered with normal heat transfer. The horizontal roof tubes in the upper portion of the boiler are also prone to sluggish coolant flow. Both of these factors lead to increasing tube metal temperatures sufficient to cause creep rupture. The examination of the tube microstructure around the failure indicated a temperature of around 480°C (900°F). These deposits led to local overheating and creep rupture on the hot side crown of the roof tube. Waterside pitting accentuated the applied tube stresses and decreased the time to rupture. The boiler should be examined for other occurrences of heavy boiler deposits. Affected roof tube sections should either be removed or the boiler chemically or mechanically cleaned.

Diesel Engines

In the diesel engine, air is compressed adiabatically with a compression ratio typically between 14 to 1 and 20 to 1. This compression raises the temperature to the ignition temperature of the fuel mixture that is formed by injecting fuel into a chamber once the air is compressed.

The ideal air-standard cycle is modeled as a reversible adiabatic compression followed by a constant pressure combustion process, then an adiabatic expansion as a power stroke and an isovolumetric exhaust.

A diesel engine designates a reciprocating engine where air is compressed within a cylinder to the extent that spontaneous ignition of fuel occurs, followed by burning a measured amount of oil-grade fuel. The compression ratio must be sufficiently high so that the air temperature at the end of compression will ignite the fuel when it is sprayed into the cylinder. Diesel engines are either two-stroke or four-stroke cycle, depending on the number of strokes required to complete a full cycle of operation. Compression ratios in the diesel engine range between 14 to 1 and 20 to 1. This high ratio causes increased compression pressures of 2760 to 4135 kPa (400 to 600 psi) and cylinder temperatures to reach 425 to 650°C (800 to 1200°F). At the proper time, the diesel fuel is injected into the cylinder by a fuel injection system, which usually consists of a pump, fuel line, and injector or nozzle. When the fuel oil enters the cylinder, it will ignite because of the high temperatures. Diesel engines are either water-cooled or air-cooled since a considerable amount of heat is generated in the cylinders and the temperature of the cylinder boundaries must be controlled to keep within safety limits. Exhaust temperatures of diesel engines are between 260 and 540°C (500 and 1000°F).

Today, diesel engines are used extensively in the military, serving as propulsion units for small boats, ships, and land vehicles. They are also used as prime movers in auxiliary machinery, such as emergency diesel generators, pumps, and compressors.

Medium-sized combatant ships and many auxiliary vessels are powered by large ($\sim 37,000 \text{ kW}$, or $50,000$ brake horsepower, bhp) single-unit diesel engines or, for more

economy and operational flexibility, by combinations of somewhat smaller engines. Diesel engines have relatively high efficiency at partial load, and much higher efficiency at very low partial load than steam turbines. They also have greater efficiency at high speeds than any of the other fossil-fueled plants. Thus they require the least weight of fuel for a given endurance. Other advantages include low initial cost and relatively low rpm, the latter resulting in small reduction gears. Additionally, diesel engines can be brought on-line from cold conditions rapidly. They are reliable and simple to operate and maintain, having a long history of active development for marine use.

In general, however, the use of diesels on intermediate-sized combatants and larger vessels requires that several smaller units be combined to drive a common shaft. This requirement results in severe space and arrangement problems. Among other disadvantages is the fact that periodic engine overhaul and progressive maintenance are required. These result in frequent down periods, which, because of the number of similar units, may increase the amount of necessary in-port maintenance time and decrease the amount of time the ship has full power available while at sea. Finally, the marine diesel has a high rate of lubricant oil consumption, which may approach 5% of the fuel consumption; thus large quantities of lubricant oil must be carried. Ship propulsion systems employ many different arrangements of engines, shafts, reduction gears, and propellers to suit the operating requirements of the ships they serve.

One of the operational characteristics of diesel engines is the ability to operate while burning a variety of fuels. Marine use of diesel fuels generally requires the use of NATO F-76 (Ref 18) diesel distillate, JP-5 turbine fuel, aviation (Ref 19), or JP-8 turbine fuel, aviation (Ref 20). When

these fuels are unavailable and to minimize operational impact, various commercial fuel grades or contract Marine Gas Oil-type fuels may be purchased under a bunker contract (local purchase) by the Defense Energy Support Center (DESC). Fuels under the bunker contract meet the Navy Marine Gas Oil (MGO) Purchase Description (PD) (Ref 21). The Navy's MGO-PD fuel is subject to standard commercial practice quality control rather than the extensive handling and storage requirements specified for MIL-SPEC fuels. The effect of sulfur content in the fuel on engine wear and performance is minimized if the engine water jacket temperature is at least 60 °C (140 °F) (Ref 21). Saltwater-contaminated fuel has caused erosion in fuel nozzles and corrosion leading to burned pistons (Ref 22).

Contamination of combustion fuel in diesel engines can cause high-temperature corrosion. When burning ash-rich and sulfur-rich fuels in engines, the exhaust gases cause considerable corrosion of the alloys surfaces to which they come in contact. The degree of corrosion is dependent on the fuel composition, on the oxygen content in the exhaust gas, and the alloy temperature (Ref 23). Vanadium and sodium contamination can cause the formation of coke deposits on high-temperature components that reduce cooling engine capacity and lead to higher exhaust gas temperatures. The formation of molten sodium vanadates at temperatures as low as 535 °C (995 °F) may lead to the high-temperature corrosion of diesel engine components (Ref 23).

Cylinder wear is due mainly to friction, abrasion, and corrosion. Frictional wear occurs between the sliding surface of the cylinder liner and piston rings. The degree of wear will depend on the materials involved, the surface conditions, efficiency of the cylinder lubrication, piston speed, engine loading with corresponding pres-

sures and temperatures, maintenances of the piston rings, combustion efficiency, and air or fuel contamination (Ref 24). If the cylinder is operated with excessive wear, the degradation may lead to gas blowpast. Gas blowpast may remove the lubricating oil film, the piston rings may distort and break, and piston slap may cause scuffing. Reduced compression causes incomplete combustion, which can lead to exhaust system fouling.

Corrosion occurs mainly in engines that burn heavy fuels that contain significant sulfur levels. The combustion of heavy sulfur-containing fuels forms acids. Sulfuric acid may condense and cause corrosion in the lower part of the liner if the jacket cooling water temperature is too low. Water vapor condenses on the liner and absorbs any sulfur species such as SO_3 or SO_2 to form the sulfuric acid. Increasing the jacket temperature above the dew-point temperature prevents this form of corrosion.

Abrasion may take place from the hard-particle products of mechanical wear, corrosion, and combustion. All fuels have a given ash content; heavy fuels tend to have a higher ash content.

Cylinder liners require adequate lubrication to reduce piston ring friction and wear. The oil film also acts as a gas seal between liners and rings and as a corrosion inhibitor. Special cylinder oil, having a high alkalinity, for engines burning heavy fuels, neutralize acids formed from the combustion of sulfur present in the fuel. Oils must maintain their viscosity at high temperatures, resist oxidation and carbonization, spread readily, yet be able to cling to working surfaces (Ref 24).

It is possible for fuel or the oil systems to be infected and contaminated by microorganisms. Their presence can generate organic acids that can lead to corrosion wear of metal surfaces and create sludge and slime that will plug oil filters.

This contamination can be minimized if cleanliness and care are exercised.

Gas Turbine Engines

The gas turbine was developed generally for main propulsion and power for certain auxiliary systems of aircraft, ships, or certain other military platforms that require a higher power density than diesel engines can generate. In the case of gas turbines, fuel and air quality and the specific engine environment in which it operates influence the corrosion of turbine components significantly. The gas turbine operates on the principle of the Brayton cycle. A gas turbine has three major components: (1) compression of a gas (typically air), (2) addition of heat energy into the compressed gas either by directly firing or combusting the fuel in the compressed air or by transferring the heat through a heat exchanger into the compressed gas, followed by (3) expansion of the hot pressurized gases in a turbine to produce useful work (Ref 25). The compressor is a series of blades or airfoils, some rotating (rotors), some stationary (stators), that draw air in and compress it. The more rows of blades, the more the air pressure increases as it passes through the compressor stages. Typical pressures can be up to 40 times higher than atmospheric pressure.

The compressed air is pushed forward into a combustion chamber where fuel is injected with the air and it ignites. The flow and burn of the air/fuel mixture is controlled to ensure that the engine sustains a continuous flame. The expanding exhaust gases flow quickly toward the rear of the engine. For modern aircraft gas turbines, combustion temperatures above 2500 °C (4530 °F) are possible. This is well above the melting point of most alloys, so film cooling of the combustion chamber is necessary. The gases

that move out of the combustor exert force against the turbine blades (airfoils), which are connected to the compressor by shafts. The gases exiting the turbine create energy by spinning the turbine that powers the compressor to continue the process of pulling air into the engine.

Air from the compressor is used for cooling the turbine in order to maintain the metal temperatures within their design limits, while the gas flowing through the turbine may be as high as 1370 °C (2500 °F). Metal temperatures can be as high as 1150 °C (2100 °F) and require some type of protective coating. The requirement for cooling the turbine limits the ultimate thermal efficiency of the gas turbine, and technologies are being developed in the areas of materials including ceramics and enhanced cooling effectiveness in order to minimize the cooling air requirement. With more advanced materials and cooling technologies, increases in turbine inlet temperature are possible in order to increase the thermal efficiency of the cycle.

There are several types of gas turbine engines. The primary purpose of aircraft gas turbines is to generate high performance and power quickly at the expense of fuel economy. Afterburning, or reheat, increases exhaust velocity and engine thrust for short times to improve aircraft takeoff, climb, and maneuverability by injecting additional fuel in the jet pipe. Vectored thrust engines employ swiveling nozzles that can direct the gas stream from vertically downward for upward lift through an arc to horizontally rearward for conventional forward thrust. Turboshaft engines are used in helicopters, marine propulsion and auxiliary systems, and some land-based military assets. It uses a power turbine and a gearbox, though the power is transmitted directly to a variety of devices, such as the rotor system, ship or platform propulsion, or auxiliary systems.

Aeroengines use relatively pure fuels with low sulfur contents, and the air quality is generally good unless there are recurrent low altitude flights or operations over marine environments. Jet fuels JP-5 and JP-8 are substances used as aircraft fuels by the military. JP-5 and JP-8 is shorthand for jet propellants 5 and 8. JP-5 is the U.S. Navy's primary jet fuel, and JP-8 is one of the jet fuels used by the other services.

Both JP-5 and JP-8 are composed of a large number of chemicals, and both are colorless liquids that may change into gas vapor. They smell like kerosene, since kerosene is the primary component of both substances. They are made by refining either crude petroleum oil deposits found underground or shale oil found in rock.

High-temperature processes that may occur in gas turbines are dependent largely on environmental factors and the type of gas turbine engine. High-temperature processes in aircraft gas turbine engines are generally due to high-temperature oxidation or to high-temperature creep. Thermal barrier coatings (TBCs) are used to protect hot section alloys from catastrophic oxidation. There is strict compositional control of the nickel-base superalloys is used in the hot

sections of aerogas turbines. These alloys are either directionally solidified or are single crystals to improve the creep strength and prolong blade life from creep damage. High-temperature corrosion at operating temperature does not occur often, but ingestion of sea salt in naval aircraft may result in pitting and molten salt corrosion if not water-washed often. Sand may cause abrasion of turbine components. The exposure to airborne dirt such as sand and ash may introduce silicates into the engine, commonly known as CMAS ($\text{CaO-MgO-Al}_2\text{O}_3\text{-SiO}_2$), which refers to the main chemical components of calcium, magnesium, aluminum, and silicon. Molten silicate deposits can penetrate TBCs in advanced gas turbine engines due to increasing operating temperatures. Molten CMAS partially penetrates the TBC during the hot phase where the critical temperature is 1240 °C (2265 °F). Upon cooling the CMAS solidifies, degrades the coatings, and promotes spallation of the infiltrated coating. Degradation appears to involve dissolution of the porous TBC columnar grains in the silicate melt and reprecipitation of dense globular zirconia crystals. The yttria stabilizer is influenced by the silicate melt leading to the formation of monoclinic zirconia that is more prone to erosion damage and spallation. Penetration of CMAS can be substantially reduced by adding alumina, which lowers the melting point of the quaternary mixture.

Shipboard marine gas turbines operate at lower metal temperatures (500 to 1000 °C, or 930 to 1830 °F) than observed in aircraft gas turbines. Shipboard gas turbine engines also use lower-grade fuels with 0.3 to 1.0 wt% S content. Unfiltered air intake for marine gas turbines may contain up to 2600 ppm Na_2SO_4 , 19,000 ppm NaCl, and contain sand-derived deposits. Filtration may reduce the chloride and sulfate content from marine environmental air to ≤ 0.01 ppm, but that is sufficient to form Na_2SO_4 (as well as Na_2SO_4 directly created from sulfur in the fuel), which can lead to sulfidation and hot corrosion. Fuel quality may vary during the service life of the engine. The use of less refined, heavy fuels may contain up to 200 ppm V that, when combined with Na_2SO_4 , accelerates hot corrosion reactions. Engine temperatures may also vary with operational loads by 400 to 500 °C (720 to 900 °F) on going from idle to full power (Ref 26). The engine may ingest solid particles (sand, ash, dust, and sea salt) and pyrolytic carbon from uncombusted or poor combustible conditions that contribute metal wastage by erosion or impact on turbine components. Carbon may also accentuate corrosion by reducing sodium sulfate to sulfides. Thermal cycling or transient conditions may further increase the corrosivity of salt deposits by cracking protective oxide layers. The complexity of the turbine operating environment and other high-temperature applications makes it impossible to develop simple tests.

The important factors that influence hot corrosion in marine gas turbines are composition of the gas, condensate composition and deposition

rate, and temperature. In order to simulate gas turbine conditions in a low-velocity atmospheric pressure rig (LVBR), it is desirable to duplicate all the variables. However, it is not possible to duplicate them exactly due to the pressure differentials between the gas turbine (0.5 to 1.5 MPa, or 5 to 15 atm) and the burner rig at 101 kPa (1 atm) LVBR (Ref 27). The corrosion rate depends on the salt deposition rate, which is nonlinear, and the corrosion depends on the composition of the salt and the substrate alloy or coating (Ref 28).

Experiences in the 1960s and 1970s led to the discoveries of severe high-temperature corrosion in shipboard gas turbine engines that usually did not occur in aircraft turbine engines. Early observations noted severe corrosion attack on the first-stage blade and vane components of a shipboard marine gas turbine engine was sufficiently rapid to cause engine failure in several hundred hours (Ref 28). The ingestion of sea salt and the combustion of fuels containing some measure of sulfur by gas turbine engines operating in marine environments can lead to corrosion of hot section components, particularly turbine vanes (nozzles) and blades (buckets). This attack was documented in the early open literature as hot corrosion as discussed earlier (Ref 29–31).

Hot corrosion is a complex process involving both sulfidation and oxidation (Ref 32). Hot corrosion is a form of accelerated oxidation that affects alloys and coatings exposed to high-temperature gases contaminated with sulfur and alkali metal salts (Ref 33). These contaminants combine in the gas phase to form alkali metal sulfates; if the temperature of the alloy is below the dew point of the alkali sulfate vapors and above the sulfate melting points, molten sulfate deposits are formed (Ref 33). Molten sodium sulfate is the principal agent in causing hot corrosion (Ref 34, 35). Sulfide formation results from the interaction of the metallic substrate with a thin film of fused salt of sodium sulfate (Ref 36–38). Sulfur compounds come from two sources in a marine gas turbine engine: (a) sulfur from the combustion fuel that often ranges from 0.1 to 1 wt% (or more) depending on the grade of fuel, and (b) sulfate salts contained in the marine air that are ingested into the hot section of the turbine engine.

Chloride salts can act as a fluxing agent and dissolve protective oxide films or cause alloy oxides to fracture and spall. Air in a marine environment ingested into the combustion zone of any marine gas turbine engine will be laden with chlorides unless properly filtered. Sodium chloride has been viewed as an aggressive constituent in the hot corrosion of gas turbine components in the marine environment (Ref 39, 40).

Two general forms of sulfate hot corrosion exist. Type I, high-temperature hot corrosion (HTHC) occurs through multiple mechanisms. It is generally thought to transpire by basic fluxing and subsequent dissolution of the normally protective oxide scales by molten sulfate deposits

that accumulate on the surfaces of high-temperature components such as hot section turbine blades and vanes. High-temperature hot corrosion usually occurs at metal temperatures ranging from 850 to 950 °C (1560 to 1740 °F). Type I hot corrosion involves general broad attack caused by internal sulfidation above 800 °C (1470 °F); alloy depletion is generally associated with the corrosion front. This basic fluxing attack may involve raising the Na₂O activity in the molten sulfate by formation of metal sulfides (Ref 41). Basic fluxing may also occur above 800 °C (1470 °F) when p_{SO_3} is low since the basicity of the molten sulfate deposits is controlled primarily by the partial pressure of sulfur trioxide, p_{SO_3} . As the reaction proceeds, the SO₂ + O₂ concentration determines if the sulfate-induced hot corrosion is sustained. Very small amounts of sulfur and sodium or potassium can produce sufficient Na₂SO₄ or K₂SO₄. In gas turbine environments, a sodium threshold level below 0.008 ppm by weight precluded type I hot corrosion (Ref 42).

Type II, low-temperature hot corrosion (LTHC) occurs in the temperature range of 650 to 750 °C (1200 to 1380 °F) where p_{SO_3} is relatively high or melts are deficient in the oxide ion concentration leading to acidic fluxing of metal oxides that results in pitting attack (Ref 43). Sulfides are found in the pitted area when nickel-base alloy are utilized (Ref 44). The LTHC may involve a gaseous reaction of SO₃ or SO₂ with CoO and NiO that results in pitting from the formation of low-melting mixtures of Na₂SO₄ and NiSO₄ or Na₂SO₄ and CoSO₄ in Ni-Cr, Co-Cr, Co-Cr-Al, and Ni-Cr-Al alloy systems (Ref 42, 45). The interaction of these oxidation products with salt deposits forms a complex mixture of salts with a lower melting temperature (Ref 46). When the salt mixture melts, the corrosion rate increases rapidly. If other reactants are added, melting temperatures of the resultant salts can be further lowered. High chromium content (>25 to 30 wt% Cr) is required, generally, for good corrosion resistance to hot corrosion. Nickel-base alloys with both chromium and aluminum show further improvement in hot corrosion resistance.

Acid-base oxide reactions with molten sulfate through the measurement of oxide solubilities as a function of Na₂O activity in fused Na₂SO₄ were examined by Rapp (Ref 47). Oxide solubility is dependent on Na₂O activity, which also serves to rank the acid-base character of individual oxides.

Other impurities such as vanadium (≥0.4 ppm), phosphorus, lead, chlorides, and unburned carbon can be involved in lowering salt melting temperatures, altering the sulfate activity, or changing the solution chemistry and acidity/basicity that leads to accelerating hot corrosion. Vanadic hot corrosion appears to be potentially more complex because five compounds exist in the Na-V-O system (Ref 48). The high-temperature reaction of sulfate and vanadium with ceramic oxides involved a Na₂O-V₂O₅ system can be explained by Lewis acid-

base chemistry (Ref 49). Basic zirconia (ZrO₂) stabilizing oxides such as yttria (Y₂O₃) do not react with Na₃VO₄ (or 3Na₂O-V₂O₅), but do react with the V₂O₅ component of NaVO₃ (Na₂O-V₂O₅) and V₂O₅ itself to form YVO₄ (Ref 50). Acidic oxides such as Ta₂O₅ react with the Na₂O component of Na₂VO₄ and NaVO₃ to form sodium tantalates and yield α-TaVO₅ with V₂O₅. The vanadate that is most corrosive in the initiation of vanadic attack will depend on the acidity/basicity of the coating or alloy oxide. No reaction occurs when the acid-base properties of a stabilizing oxide is equal (Ref 51). The thermochemistry of vanadate and sulfate melts and reaction with different stabilizing oxides with SO₃-NaVO₃ was studied by Jones (Ref 52).

High chromium content (>25 to 30% Cr) is required for good resistance to hot corrosion. Nickel alloys with both chromium and aluminum show improved hot corrosion resistance. However, inspection of Ellingham phase stability diagrams for the systems M-Na-O-S, where M can be nickel, cobalt, iron, aluminum, or chromium, indicates that there are no combination of melt basicity and oxygen activity where these metals, absent of a protective oxide film, are stable in contact with fused sodium sulfate (Ref 53). The relative hot corrosion resistance of a number of alloys has been evaluated in incinerator environments (Ref 54–56).

Yttria-stabilized zirconia (YSZ) is attacked and destabilized by phosphorus impurities in fuel (Ref 57). Phosphoric anhydride, also known as anhydrous phosphoric acid (P₂O₅), reacts with basic Y₂O₃ to form the salt, YPO₄. Zirconia also synergistically reacts with sodium and P₂O₅ to form NaZr₂(PO₄)₃. YSZ thermal barrier coatings have been exposed to PbSO₄-Na₂SO₄ molten salts without observable destabilization or reaction with this ceramic (Ref 58). However, lead, as PbO, appears to cause TBC failures by reacting with chromium in the NiCrAlY bond coat to form PbCrO₄.

Case Study: Turbine Blade Failure. A case study of a marine gas turbine failure centered on the extent of corrosion that occurred under the platform of a turbine blade. Figure 7 shows a failed turbine blade. Figure 8 show unfailed blades that displayed heavy deposition under the platform of the double-stemmed blade. The blade alloy was within material specifications and the corrosion-resistant coating was applied by thermal spray. Metallographic examination showed that the coating thickness under the platform and in the curved area of transition between the platform and the blade stem was either very thin (up to 40 μm thick) or non-existent. The coating, if present, usually was porous or had entrained contamination under the platform due to lack of adequate spray deposition in these non-line-of-sight areas as shown in Fig. 9. MCrAlY coating thickness at other sites along the blade stem was 35 to 105 μm.

The corrosion that was observed under the platform, in all cases, was caused by type II, LTHC, which occurs in the temperature range of

650 to 730 °C (1200 to 1350 °F). In addition to the presence of hot corrosion, cracking was observed to initiate at several hot corrosion sites (Fig. 10). This was found to be advancing to various degrees through the stem of several blades. The pitting caused by the type II hot corrosion provided initiation sites for cracking to begin and reduced the overall undamaged cross section at the stem, thus increasing the applied stress to the corroded area. The cracking initially advanced via corrosion fatigue, but later, in some blade cases, by high-cycle fatigue (Fig. 11). Some cracking proceeded through both blade stem walls, causing some blades to break off during service. Many of the “unfailed” blades exhibited evidence of hot corrosion and varying degrees of corrosion fatigue/fatigue cracking.

Incinerators

Incinerators are used to manage wastes in an efficient manner rather than sending these waste materials to a landfill or accumulating the wastes aboard ship. Military (land-based) incinerators must comply with various regulations for operation and for management of residual wastes and the gaseous emissions. Compliance with local, national, and international (such as the International Treaty for the Prevention of Pollution for Ships/Marine Pollution Protocol, MARPOL) environmental regulations and statutes controlling overboard discharge of liquid wastes, sanitary wastes, and air emissions have become more stringent for ships deployed at sea.

Among the many issues involved, the reliability and design of incinerators will depend on the materials of construction. One of the primary operational factors is the corrosion resistance of candidate materials; the discussion of many of the other issues is beyond the scope of this article. Complex processes occur in incineration of solid wastes, which involve thermal and chemical reactions that occur at various times, temperatures, and locations. Pyrolysis via high reaction temperatures derived from plasma energy will also encompass complex reactions, dynamic gas flows, particulate and deposition effects, mechanical and chemical mixing, and residence times of the reaction species. The operational mode, the temperatures existing within the primary combustion chamber, secondary combustion, and other system components, composition of the waste stream, the chamber chemical environment, the waste stream abrasiveness, the aforementioned space constraints, safety, maintainability, and reliability will affect the choice of construction materials.

Incinerators also contain inherently complex high-temperature environments. The corrosiveness of the incinerator environment depends on the relative stream of wastes that are generated and the efficiency of removing potential wastes that have been proven to be severely corrosive,

such as chlorine-containing plastics. High-temperature corrosion was observed in shipboard waste incinerators (Ref 55, 59).

Incinerator design generally considers two types of operating scenarios using two classes of materials. They are primarily refractory-lined incinerators and air-cooled or water-cooled alloy-lined incinerators.

A **refractory-lined incinerator** does not employ any active cooling and may operate at temperature up to 1500 °C (2730 °F). Most alloys will degrade in environments with prolonged service temperatures above 1000 °C (1830 °F). Refractories are mainly high-melting-point metallic oxides, but also include substances

such as carbides, borides, nitrides, and graphite (Table 2). Maximum service temperatures will always be less than the melting points of pure ceramics because refractories usually contain minor constituents and actual incinerator environments are vastly different from simple oxygen atmospheres. Refractories are used to act as a thermal barrier between the high-temperature environment and an ambient temperature outside the chamber skin to maximize safety to personnel. Refractory suitability depends on its resistance to abrasion, maximum service temperature, corrosion resistance to liquids, gases and slag, erosion resistance, spalling resistance, resistance to thermal cycling, shock, and fatigue from high thermal gradients, oxidation or reduction reactions, its mechanical strength, and its inspection and maintenance requirements. Refractories are available in either shaped (bricks) or unshaped, monolithic forms such as castable plastic refractories, ramming mixes, ceramic fiber blankets, or gunning mixes.

There are often property trade-offs required to attain the desired optimum, serviceable refractory. Insulating refractories generally have lower density, strength, corrosion resistance, erosion resistance, and higher porosity and void fraction than stronger, less insulating refractories. Refractories are generally susceptible to thermal shock and spalling. Monolithic refractories are often more susceptible to thermal shock than shaped refractories. Dense refractories tend to have high thermal conductivities, low porosity, relatively high strength, and improved corrosion resistance, but tend to be susceptible to thermal shock. Insulating refractories have higher porosity, which improves thermal shock resistance, but provides numerous pathways for molten and gaseous materials to promote corrosion and spalling.

The corrosion resistance of refractories will be based on the thermodynamics of the potential corrosion reactions, the reaction rates and kinetics of these possible reactions, the composition and form of the refractory material, and the surface chemistry of the refractory with corrosive gaseous, liquid, or solid environments. As with other chemical reactions, the spontaneous direction of the possible corrosion reactions can be calculated, the determination of which will indicate which reactions are theoretically possible. The kinetics will be dependent on the specific environment (gaseous, liquid, or solid), surface chemistry, the material microstructure, material composition, refractory phase(s), and the temperature. All ceramic or refractories used in an oxygen-rich environment are oxides or develop a protective oxide on their surface (such as SiO_2 on SiC , or Si_3N_4). Though oxide ceramics are chemically inert and resist oxidation and reduction, they are not inert to certain molten salts. Ceramic corrosion between ceramic oxides and molten salt deposits are primarily due to oxide acid-base reactions (Ref 48).

To determine if a particular slag is acidic or basic, the lime-to-silica ratio in the slag is commonly used. As a general rule, the slag is basic if the CaO/SiO_2 ratio (or $\text{CaO} + \text{MgO}/\text{SiO}_2 + \text{Al}_2\text{O}_3$ ratio) is greater than one. If the ratio is less than one, the slag is considered acidic (Ref 60). Gases and liquids can penetrate deeply into high porous refractories that can exacerbate spalling and accelerated corrosion. Oxidizing gases such as NO_x , Cl_2 , O_2 , CO_2 , H_2O , and SO_2 , reducing gases (NH_3 , H_2 , C_xH_y , CO , and H_2S), and vapors of volatile elements and compounds may react with different refractories. Hydrodynamic mass transport by either convection or diffusion can markedly affect the corrosion rate of a refractory in an environment. Nonwetting refractories are relatively resistant to corrosion

Fig. 7 Failed shipboard turbine at the transition between blade and stem. See also Fig. 8 through 11.

Fig. 8 Two shipboard turbine blades. Pressure side shown facing out of the page. Arrows denote areas where heavy corrosion products are observed.

Fig. 9 Blade location along curvature at platform/stem transition. Poor coating quality at this site provides easy pathways for corrosion penetration. Original magnification 200×

Fig. 11 Crack propagation direction of failed turbine blade. Corrosion propagates over 60% of the stem wall, thus increasing the applied stresses in the remaining stem wall. Fracture shows a sharp transgranular characteristic suggesting cleavage or high cycle fatigue. Original magnification 55×

with liquids or gases. High-purity refractories are more corrosion resistant because minor impurity components from secondary, phases and defect structures that can introduce significant corrosion are kept to a minimum; alkali impurities should be minimized as much as possible. High-purity refractories also improve corrosion resistance by avoiding low-melting eutectics. Solids, either as fine particulates or dust, can cause degradation of refractories through abrasion or deposition.

There are several limitations to the use of refractories in incinerators. First, a layer of a working refractory such high-purity alumina, silicon carbide, or alumina-chromia is required to be used since these refractories have the highest resistance to corrosion reactions with slag, liquids, or gases, are abrasion and spall resistant, have low porosity, and have a limited thermal shock resistance. Since these refractories also have a high thermal conductivity, an insulating refractory must be inserted between the chamber shell and the working refractory. To reduce the temperature from 1500 °C (2730 °F) on the inner wall surface to about 100 °C (212 °F) on the outer shell, the combined thickness of the two refractory layers could be 300 mm (12 in.) or more. This adds an unacceptable weight and space in applications where space is critical.

Second, refractories may crack from thermal shock and react with wastes to corrode or wear

away, thus requiring repair. Eight or more hours may be required for the crucible chamber to cool before repairs can initiate. Repair would require the use of plastic refractories, mortar materials, or patching mixes for quick repairs or a more time-consuming reinstallation of refractory brick, which may limit the location of refractory-lined incinerators.

For additional information on high-temperature corrosion of refractory materials, see the article "Performance of Refractories in Severe Environments," in *Corrosion: Materials*, Vol 13B, of the *ASM Handbook*.

Alloy-lined incinerators reduce weight and size and improve reliability, operability, and maintainability while maintaining environmental compliance and maintaining safety. The gas temperature in the primary chamber may be up to 1200 °C (2190 °F) with possible hot spots above 1370 °C (2500 °F). An alloy-lined incinerator will be actively cooled by water. Thermal shock may occur during start-up or shutdown, particularly if the incinerator is not operated properly. Thermal shock may also be experienced if cooling water leaks occur. The chamber environment would contain N₂, CO₂, H₂O vapor, NO_x, and small quantities of alkalis and acid gases (HCl, SO₂). Particulates in the gas stream could cause erosion and abrasion damage. While conventional refractory-lined incinerator may be more than 300 mm (12 in.) thick, an alloy-lined

incinerator wall may be 13 mm (0.5 in.) thick using a superalloy such as alloy 718 (UNS N07718). Table 3 shows possible alloys that may be used for alloy liners for incinerators.

Shipboard incinerators used for the disposal of blackwater (sewage) may utilize alloy 690 (Ni-30Cr-9Fe UNS N06690) operating at a peak temperature of 760 °C (1400 °F). The ability of the liner alloy to resist corrosion is dependent on its protective surface oxide film. Conditions that can damage the oxide and the substrate alloy may include: (a) alternating oxidizing and reducing environments at high temperatures, which may interfere with oxide formation and oxide maintenance resulting in porous films, (b) mechanical stresses such as residual stresses derived from fabrication and welding processes, cyclic thermal stresses that deform the alloy substrate because of rapid cooling rates, or crack or spall the oxide layer because of tensile or compressive stresses, (c) impingement/erosion that removes the oxide when fluid (gas or liquid) flow exceeds a threshold velocity, (d) reaction with corrosives, moisture condensation, (e) deposits of low-melting point mixtures, (f) flame impingement, (g) crevices or defects encouraging galvanic attack, (h) changing metal properties from prolonged exposure at high temperatures, (i) molten chlorides, and (j) molten alkali sulfates (Ref 60). Reaction of the slag with the chamber wall must also be considered. Corrosion in waste incinerators has also been discussed in detail previously (Ref 55, 56, 63–70).

Most metals and alloys in an oxidizing environment are protected to varying degrees by an oxide layer. Iron oxides alone are not protective above 550 °C (1020 °F) (Ref 71). Oxidation of carbon steels from air or steam forms an oxide scale along the metal surface that grows and thickens with time. The scales, depending on chemical composition, can be mildly insulating to very insulating. The scale growth rate increases with a rise in temperature. Chromium, aluminum, and/or silicon assist in forming scales that are more protective at higher temperatures (Ref 61). Depending on flow rate and the pO₂,

Table 2 Melting points of common refractories

Nomenclature	Formula	Melting point	
		°C	°F
Corundum, alpha alumina	Al ₂ O ₃	2054	3729
Baddeleyite, zirconia	ZrO ₂	2700	4892
Periclase, magnesia	MgO	2852	5166
Chromic oxide, chromia	Cr ₂ O ₃	2330	4226
Lime, calcia	CaO	2927	5301
Cristobalite, silica	SiO ₂	1723	3133
Carborundum, silicon carbide	SiC	2700 (sublimes)	4892 (sublimes)
Silicon nitride	Si ₃ N ₄	1800 (dissociates)	3272 (dissociates)
Boron nitride	BN	3000 (sublimes)	5432 (sublimes)

chromium oxide is stable up to 983 °C (1801 °F), above which the oxide volatilizes to gaseous CrO_3 . Mechanical damage by spallation or cracking of the oxide film from cyclic oxidation of chromia and alumina oxides formed on nickel-base alloys is due to the mismatch of thermal expansion coefficients between the oxide and the base alloy (Ref 63). Small additions of lanthanum, yttrium, tantalum, ceria, zirconia, and/or niobia improve the scale adhesion and scale resilience to cyclic oxidation (Ref 71).

The incinerator alloy material reportedly may be protected from molten slag by an oxide/slag skull. However, in the event of possible contact with molten slag, it is important to know the corrosion resistance to slag of the candidate materials. Liquid metal corrosion may cause dissolution of a surface directly, by intergranular attack, or by leaching. Liquid metal attack may also initiate alloying, compound reduction, or interstitial or impurity reactions. Carbon and low-alloy steels are susceptible to various molten metals or alloys such as brass, aluminum, bronze, copper, zinc, lead-tin solders, indium, and lithium at temperatures from 260 to 815 °C (500 to 1500 °F). Plain carbon steels are not satis-

factory for long-term usage with molten aluminum. Stainless steels are generally attacked by molten aluminum, zinc, antimony, bismuth, cadmium, and tin (Ref 72).

Nickel, nickel-chromium, and nickel-copper alloys generally have poor resistance to molten metals such as lead, mercury, and cadmium. In general, nickel-chromium alloys also are not suitable for use in molten aluminum (Ref 73). Liquid metal embrittlement (LME) is a special case of brittle fracture that occurs in the absence of an inert environment and at low temperatures (Ref 74). The selection of fabricating processes must be chosen carefully for nickel-base superalloys.

Case Study: Corrosion in a Waste Incinerator. A failed uncoated alloy 690 incinerator liner was removed from service. The incinerator liner had been in service for an estimated 264 h before being repaired with a patch of alloy 160 plate (13 mm, or 0.5 in., thick) tack welded over the alloy 690 incinerator liner hole. About 382 h of additional service were clocked on this incinerator before its removal. Figure 12 shows that ash deposits covered the entire inner alloy

690 incinerator liner surface and the degree of deterioration of the alloy 690 liner around the alloy 160 patch.

The uncoated liner developed a very large perforation on the liner directly under the burner head where the incinerator flame could impact the liner surface, but inspection of this liner also revealed other, smaller perforations at numerous locations and elevations. The plate had not experienced any appreciable, visible corrosion after its 265 h of shipboard incinerator service. The alloy 690 liner adjacent to the alloy 160 patch showed severe deterioration and thinning of the liner wall, which had reduced the liner thickness from 6.4 mm (0.25 in.) to less than 0.51 mm (0.020 in.). Figure 13 displays generalized, uniform corrosive penetration about 0.125 to 0.20 mm (0.005 to 0.008 in.) deep into the alloy 690 liner that was caused by sulfidation. The major, outer, unexposed portion of liner alloy at this site was undisturbed. The surface corrosion had initiated at the inner, exposed liner surface; corrosants penetrated and advanced along the grain boundaries and combined with intragranular species to form oxide/sulfide precipitates.

Sulfidation led to corrosion and thinning of the incinerator wall and the diffusion of sulfur into the liner weakened the overall alloy mechanical strength and led to loss of ductility of the local microstructure. This induced an increased susceptibility to fatigue or corrosion fatigue cracking from cyclic thermal stresses from incinerator operation as shown in Fig. 14. Sulfidation and hot corrosion caused a large perforation of the liner under the burner head. Remaining perforated and pitted sections of the uncoated liner displayed varying degrees of attack from sulfidation and

Fig. 12 Failed incinerator liner. Hole near alloy 160 patch shows that the original 6.4 mm (0.250 in.) wall thickness had been reduced to 1.3 mm (0.050 in.) or less in the general area. See also Fig. 13 through 15.

Fig. 13 Uncoated incinerator liner. Diffusion of sulfur species along the grain boundaries has led to sulfidation of the liner alloy. Sulfur species concentration decreases as it moves deeper into the alloy. Original magnification 250×

Fig. 14 Uncoated incinerator liner near failure. Corrosion penetration from both inner and outer surfaces accompanied by cracking of liner. Total wall thickness has been reduced to 350 μm (0.014 in.). Some grain reorientation and corrosion products are present. Original magnification 50×

Fig. 15 Uncoated incinerator liner. Diffusion of sulfur species extends about 250 to 300 μm (0.01 to 0.012 in.) into the liner alloy. Severe sulfidation and type II hot corrosion had penetrated about 175 μm (0.007 in.) into the liner alloy. Original magnification 250×

hot corrosion. Figure 15 shows that diffusion of sulfur penetrated about 0.25 to 0.30 mm (0.01 to 0.012 in.) into the liner alloy. Severe sulfidation and type II hot corrosion had penetrated about 0.175 mm (0.007 in.) into the liner alloy. Debris blocking the air cooling channel between the inner and outer liners raised the overall alloy liner temperature and exacerbated the high-temperature corrosion. Sulfur species reacted with alloy 690 constituents at breaks in the surface oxide. Those sites affected by sulfidation were susceptible to cracking and accelerated wall loss and thinning. Alloy 160 appeared to offer some improvement in hot corrosion resistance over alloy 690.

Finishing Systems for Naval Aircraft

Kevin J. Kovaleski and David F. Pulley, Naval Air Warfare Center, Aircraft Division

EXTERIOR COATINGS provide corrosion protection, camouflage, erosion resistance, markings, electrical grounding, electromagnetic shielding, as well as other specialized properties. Protective coatings serve as the primary defense against the corrosion of metallic alloys as well as the degradation of other materials (such as polymeric composites and plastics) (Ref 1). Traditional coatings for aircraft include inorganic pretreatments, epoxy primers, and polyurethane topcoats. Pretreatments provide some corrosion protection and prepare the surface for subsequent organic coatings. Primers normally contain high concentrations of corrosion inhibitors such as chromates and are designed to provide superior adhesion. Polyurethane topcoats enhance protection and durability while providing the desired optical effects, including camouflage.

More recently, alternative coatings have been developed, such as nonhexavalent chromate pretreatments and primers, flexible primers, advanced performance topcoats, self-priming topcoats, low volatile organic compounds (VOCs) coatings, temporary coatings, and multifunctional coatings. These new developments reflect trends in protective coatings technology, changes in aircraft operational requirements and capabilities, and concerns over environmental protection and worker safety. Environmental issues have created a drive toward coatings with ultralow/zero concentrations of VOCs and non-toxic corrosion inhibitors. In turn, these changes have led to concerns over long-term performance, especially protection against corrosion. Current protective coatings technology, future needs, and trends based on advancing technology, environmental concerns, and operational requirements are included in this article.

Coatings life is critical. An Air Force study (Ref 2) concluded that "The rate-controlling parameter for the corrosion of aircraft alloys, excluding the mechanical damage factor, is the degradation time of the protective coating system." Navy aircraft face a unique and harsh environment because they are deployed at coastal land bases or onboard aircraft carriers. The continuous proximity to saltwater and high humidity, combined with atmospheric impurities, results in one of the most corrosive natural environments. In addition, many operational and

maintenance chemicals commonly used or found on aircraft, such as paint strippers, battery acid, deicing fluids, and cleaners, are corrosive. These effects are exaggerated with aging fleet aircraft that have flown many flights over long periods of time, adding fatigue as another factor. Considering the high cost of these aircraft (in addition to fewer numbers of new aircraft programs), materials protection is of the utmost importance.

While traditional coatings possess exceptional corrosion inhibition, adhesion, and durability characteristics, these coating systems have been identified as a major contributor to the generation of hazardous materials and hazardous waste for the Navy (Ref 3). Volatile organic compounds, such as carrier solvents plasticizers, and heavy metal compounds, such as corrosion inhibitors and colorants, are being severely regulated, and coating formulations are being drastically changed. These changes have led to concerns over long-term performance. The typical lifetime of these coatings for deployed aircraft is approximately 4 years, after which the coating system is removed. The aircraft surface is then cleaned, pretreated, and recoated.

Standard Finishing Systems

The following is a description of the specific finishing systems being used on Navy aircraft and future trends for these materials. More general information is provided in Ref 4 to 8.

Surface Pretreatment. The primary goal of surface preparation and pretreatment processes is to enhance the corrosion resistance and adhesion of subsequent organic coatings. Proper surface preparation is an important step in the protection of aluminum and is accomplished using materials such as alkaline cleaners, etchants, and deoxidizers. These materials remove organic contamination along with the existing surface oxide layer of the aluminum to prepare it for subsequent chemical pretreatments.

MIL-S-5002, "Surface Treatments and Inorganic Coatings for Metal Surfaces of Weapon Systems," is the military specification for the surface preparation and pretreatment of virtually every Navy aircraft and weapon system. The two primary surface pretreatments for naval aircraft are chromate conversion coatings and anodic films. Chromate conversion coatings (CCCs) are excellent surface pretreatments for aluminum alloys. These materials chemically form a surface oxide film (typically 430 to 650 mg/m², or 40 to 60 mg/ft²), which enhances the overall adhesion and corrosion protection of the finishing system applied over it. Typical CCC film performance requirements are covered by MIL-C-5541, "Chemical Conversion Coatings on Aluminum and Aluminum Alloys," and CCC material properties are described in MIL-DTL-81706, "Chemical Conversion Materials for Coating Aluminum and Aluminum Alloys." Anodize processes form a thicker oxide film (2200+ mg/m², or 200+ mg/ft²) by electrochemical means, providing more protection against degradation in comparison to chemical conversion coatings. Anodize processes are performed in accordance with MIL-A-8625.

Primer. Epoxy resins are commonly used as binders in high-performance primers due to their exceptional adhesion and chemical resistance. The solvent-borne epoxy primer is manufactured and packaged as a two-component epoxy/polyamide system. One component contains an epoxy resin that is the product of a condensation reaction between epichlorohydrin and bisphenol-A. The second component contains a multifunctional polyamide resin. After mixing the two components, the reaction of epoxide and amide groups within the resins (R) ensues according to Fig. 1.

The product of this reaction is a highly cross-linked polymer that forms the matrix of the primer film. The chemical and mechanical properties of the epoxy matrix cause the primer to be adherent, chemically resistant, and durable.

Fig. 1 Chemical reaction for a typical two-part epoxy coating. R and R' are multifunctional polymeric units.

Hydroxyl groups on the solid epoxy are usually given credit for the excellent adhesion of these coatings. Detailed discussions of epoxy resin chemistry are found in the article "Organic Coatings and Linings" in *ASM Handbook*, Volume 13A, 2003, as well as in Ref 9 and 10.

The epoxide component of the primer contains various pigments, including titanium dioxide, strontium chromate, and extender pigments. Strontium chromate is the most critical of these pigments, because it is known as an exceptional corrosion inhibitor, especially for aluminum. Titanium dioxide in the primer enhances durability, chemical resistance, and opacity of the applied coating. The extender pigments can be silicas, silicates, carbonates, or sulfates. The extenders are normally inexpensive and provide a cost-effective component that fills the coating and reduces the gloss of the applied film. The surface irregularities that cause gloss reduction also act as anchors for a topcoat, thus enhancing inter-coat adhesion by improving the mechanical attachment. References 6 and 7 provide a comprehensive review of epoxy primer technology for aircraft applications.

On mixing the two components of the epoxy/polyamide primer, the curing reaction begins. After a dwell time of 30 min, the coating is suitable for spray application. The coating is applied to a dry-film thickness of 15 to 24 μm (0.6 to 0.9 mil). The coating is tack-free within 1 to 5 h and dry-hard within 6 to 8 h. For corrosion-prone areas, the primer may be applied up to double this thickness. If a topcoat is to be applied, it is usually accomplished within the tack-free to dry-hard time period to ensure proper adhesion. The primer attains sufficient dry-film properties within 7 to 14 days of application.

Adhesion of the primer is determined according to ASTM D 3359 by a tape test after 24 h immersion in distilled water (Ref 11). There should be no coating removal from the substrate. Adhesion is also characterized by a method that quantifies the force required to scrape the primer from the substrate, ASTM D 2197 (Ref 12). Typically, scrape-adhesion values of at least 3 kg (7 lb) are considered acceptable. Other adhesion tests employed in research and development laboratories are the tensile adhesion and Hesiometer knife-cutting tests (Ref 13). These sophisticated laboratory adhesion tests yield quantitative data but require more training and expertise to perform the tests and analyze the data, compared to the tape and scrape-adhesion tests.

Corrosion resistance is evaluated by applying the primer to chromate-conversion-coated aluminum substrates, such as 2024-T3 alloy. After curing for 7 to 14 days, the primer is scribed with an "X" so that the substrate is exposed. Resistance to 5% NaCl salt fog exposure (ASTM B 117) requires that no substrate corrosion or coating defects are produced after 2000 h exposure. Resistance to filiform corrosion is evaluated on primed and topcoated test panels. After exposure to hydrochloric acid for

1 h, the panels are exposed to high humidity for 1000 h. Generally, specimens should not exhibit any filiform growth from the scribe greater than 6.35 mm (0.25 in.), with the majority less than 3.175 mm (0.125 in.). Sulfur dioxide/salt fog exposure (ASTM G 85, annex 4), cyclic wet/dry exposure, and electrochemical impedance spectroscopy have also been used to evaluate the corrosion resistance of coating systems. The performance requirements for the standard solvent-borne epoxy primer are specified in specification MIL-PRF-23377, "Primer Coatings: Epoxy, High-Solids."

High-performance waterborne epoxy primer, which is currently used on the exterior surfaces of many military aircraft, was developed (Ref 14) and implemented in the Navy community in the late 1970s to mid-1980s. This primer is procured under specification MIL-PRF-85582, "Primer Coatings: Epoxy, Waterborne." The primer is supplied as a two-component epoxy/polyamide or epoxy/amine system. The resin systems are water-reducible, and film formation occurs via coalescence of resin particles and cross linking of the epoxy/polyamide or amine reactive groups. The pigments used are similar to those used in the solvent-borne primer system. Both strontium and barium chromates are used as the primary corrosion inhibitors in waterborne primers. Organic cosolvents and surface active agents are also used to enhance formulation and processing properties, such as water miscibility, dispersion stability, film formation, and surface finish.

Brittleness. The epoxy primer is brittle, especially at low temperatures (-51°C , or -60°F). This can result in extensive cracking of the paint system in highly flexed areas of the aircraft. Sealants, which are sometimes spray-applied between the primer and topcoat in aircraft finishing systems to increase overall coating flexibility, are soft, easily deformed, and difficult to apply and remove. An alternative is an organic coating that possesses the adhesion of a primer and the flexibility of a sealant, thus eliminating the logistical and application problems inherent in stocking and applying two materials instead of one. An elastomeric primer that provides these benefits has been characterized (Ref 15) and implemented on Navy aircraft. This technology conforms to specification TT-P-2760, "Primer Coating: Polyurethane, Elastomeric." This material is based on polyurethane resin technology, a pigment system containing strontium chromate for corrosion inhibition, and extender pigments for gloss control. Most of the requirements for this flexible primer are similar to those in the current epoxy primer specifications, with the exception of film flexibility. This requirement is significantly more stringent than the current epoxy primers: 80% versus 10%

elongation, respectively. One of the major coating failure mechanisms on aircraft is cracking around fasteners, thus exposing bare metal. Application of this coating to numerous Navy and Air Force aircraft has resulted in fewer coating system failures due to cracking and chipping.

Topcoat. A high-performance topcoat, conforming to specification MIL-PRF-85285, "Coating: Polyurethane, Aircraft and Support Equipment," is applied to Navy aircraft in order to enhance protection against the operational environment. Aliphatic polyurethane coatings are ideal for this application due to their superior weather and chemical resistance, durability, and flexibility. These urethanes are two-component reactive materials. One component of the coating is a polyisocyanate resin or an isocyanate-terminated prepolymer based on hexamethylene diisocyanate. The second component contains hydroxylated polyester. On mixing, the isocyanate groups react with the hydroxyl groups of the polyester, as shown in Fig. 2.

The resulting polymer is flexible yet extremely durable and chemical resistant. Aliphatic isocyanates and polyesters are used in topcoats because they provide outstanding weather resistance compared to epoxies, whose aromatic groups degrade when exposed to ultraviolet light. References 16 to 19 provide more detailed discussions about polyurethane chemistry. When the two components are combined and the polyurethane reaction begins, the coating is ready for application (i.e., no induction time is required). This coating is normally spray-applied to a dry-film thickness of $50.8 \pm 7.6 \mu\text{m}$ (2.0 ± 0.3 mils). The typical topcoat is set-to-touch and dry-hard (when cured at room temperature) within 2 and 8 h, respectively. Although the painted surface can be handled after 6 h without damage to the coating, full properties are normally not obtained until approximately 7 to 14 days.

The most critical performance requirements for topcoats are weather resistance, chemical resistance, and flexibility. Weather resistance is evaluated by laboratory exposure in an accelerated weathering chamber (Ref 20) for 500 h according to ASTM G 155. Exposure in this chamber consists of cycles of 102 min of high-intensity ultraviolet light (xenon arc) followed by 18 min of combined ultraviolet light and water spray. Although studies have shown that there is no precise correlation with outdoor exposure (Ref 21–23), the accelerated exposure does indicate if the coating is susceptible to ultraviolet and/or water degradation. Both accelerated and real-time weathering conditions cause only minimal changes in the color, gloss, and flexibility of high-performance aircraft topcoats.

Fig. 2 Chemical reaction for a typical two-part polyurethane coating. R and R' are repeating polymer chains.

Chemical stability is evaluated by exposure to various operational fluids, such as lubricating oil, hydraulic fluid, and jet fuel, at elevated temperatures and/or extended durations. Aerospace topcoats are also subjected to heating at 121 °C (250 °F) for 1 h. Topcoats should show no defects other than slight discoloration after exposure to these conditions.

Flexibility requirements for polyurethane topcoats include impact and mandrel-bend tests. For high-gloss colors, 40% elongation of the coating after impact at room temperature and a 180° bend around a 2.54 cm (1.0 in.) cylindrical mandrel at -51 °C (-60 °F) are required without cracking of the film. Flexibility requirements for low-gloss colors are less stringent at low temperatures, because it is difficult to formulate flexible, low-gloss coatings due to the high pigment concentrations.

Advanced-Performance Topcoat. Aircraft coatings tend to degrade in their operational environment, as evidenced by discoloration, chalking, dirt accumulation, and corrosion. Continual corrosion repairs and cosmetic touchup yield a patchy appearance. The weight of excess paint reduces aircraft speed and range. Eventually, the aircraft must be sent to a depot for complete repainting and is therefore out of service for several months. Fluorinated polymers are known for their excellent environmental stability. A fluoropolymer resin can be combined into a conventional polyurethane topcoat to produce a coating with greatly improved weather resistance. In laboratory tests, such a coating showed superior resistance to fading and chalking after 3000 h of accelerated weathering. A durable topcoat would help to extend aircraft service life (time between rework cycles) and reduce maintenance costs. If the current 3 to 4 year life of these coatings could be increased to 8 years, half of the rework due to paint degradation would be eliminated, and maintenance costs would be greatly reduced. Boeing estimated a cost saving of \$760,000 per depot cycle for a C-17 aircraft.

Self-priming topcoat (SPT) is a VOC-compliant, nonchromate, high-solids polyurethane coating that was designed to replace the current primer/topcoat paint system used on aircraft (Ref 24). This technology conforms to TT-P-2756, "Polyurethane Coating: Self-Priming Topcoat, Low Volatile Organic Compounds (VOC)." The SPT possesses the adhesion and corrosion-inhibition properties of a primer as well as the durability of a topcoat. The SPT effectively eliminates the need for a primer and thus reduces the application time and materials. In addition, the hazardous emissions and toxic wastes associated with current primers are eliminated. The specified thickness of this film is 50.8 to 66.0 µm (2.0 to 2.6 mils). It has been successfully applied to a variety of operational Navy aircraft, such as the F-14, F-18, AV-8, H-3, H-46, and P-3. These materials, however, are more sensitive to surface preparation and have raised issues regarding adhesion and corrosion protection.

Specialty coatings are used to address specific concerns.

Sealants. Although the current epoxy primers provide excellent adhesion and corrosion inhibition, they are brittle. This lack of ductility may result in cracking of the paint system on highly flexed areas of the aircraft. In order to improve the overall flexibility of the epoxy primer/polyurethane topcoat coating system, sealants are frequently incorporated into aircraft finishing systems. These sprayable materials are applied between the primer and topcoat up to 203 µm (8 mils) thickness and are primarily formulated from polysulfide, polyurethane, and polythioether binders. Their elastic nature minimizes cracking of the paint system. Critical requirements in these specifications are low-temperature flexibility (mandrel-bend tests), chemical resistance (fluid immersion at elevated temperatures), and corrosion resistance (5% NaCl salt spray tests). Although these sealants provide corrosion protection by the formation of a relatively impermeable barrier, some sealants also contain strontium chromate for corrosion inhibition. A detailed discussion of this technology can be found in Ref 25 and 26.

Rain-Erosion Coatings. Rain droplets and airborne debris (sand and dust) can impact aircraft leading edges and radomes during flight. The force of impact from these particles can erode the coating system and adversely affect the underlying substrate. The current primer/topcoat and SPT paint systems do not provide adequate protection against erosion, even when applied at two to three times its normal thickness.

The rain-erosion-resistant coating used on Navy aircraft is a two-component polyurethane material. One component consists of a pigmented, high-molecular-weight, polyether-type polyurethane. The other component contains a clear ketimine (blocked diamine) resin that acts as both a cross-linking agent and a chain extender. When combined, the two components form an elastomeric coating that can absorb and dissipate the energy of impacting rain droplets, thus preventing failure. Flexibility is characterized by a 0.635 cm (0.25 in.) mandrel bend at -51 °C (-60 °F) and tensile elongation of 450%. However, in order to exhibit this high elasticity, the polymer cross-link density is decreased, yielding reduced chemical resistance and weathering properties. In order to improve the finishing system durability, these materials are usually overcoated with the standard topcoat.

Although elastomeric coatings offer increased resistance to rain erosion, elastomeric tapes provide the optimal protection for Navy aircraft. These materials can be clear or pigmented polyurethane-based films supplied with or without an adhesive backing. Unlike coatings, these tapes are bonded to the surface. Early versions of these materials were clear aromatic-type polyurethanes. Although durable, these aromatic materials had poor weatherability. The newer aliphatic versions are extremely durable and have excellent weatherability.

High-temperature-resistant coatings are needed at various areas of Navy aircraft that are routinely subjected to elevated temperatures. The standard paint system was only designed to resist thermal exposures up to 176 °C (350 °F) for short durations. The only organic coatings able to resist high temperatures contain silicone binders. These silicone coatings contain aluminum flakes as pigment and are designed to withstand temperatures up to 650 °C (1200 °F). They can be applied by conventional air spray and are cured by heating to 204 °C (400 °F) for 1 h or upon reaching elevated temperatures during component operation. During the curing period, the binder system for this coating will oxidize, leaving a barrier layer of silicone oxide/aluminum to protect the underlying substrate from adverse conditions. Although this material provides adequate barrier protection, it is relatively soft and easily damaged in service.

Fuel Tank Coatings. Aviation fuels contain additives that may be corrosive. If left unprotected, fuel tanks would corrode and leak. In order to protect the tank interior, polyurethane fuel tank coatings are typically used. These highly cross linked chemically resistant coatings are two-component materials designed for application to nonferrous surfaces. The fluid resistance requirements for these materials are significantly more severe than those for the standard primer and topcoat. The higher degree of chemical resistance is necessary, because the fuel tank temperature can reach as high as 120 °C (250 °F) and the coating is not only subjected to various chemicals contained in aviation fuels but also to aircraft operational chemicals, saltwater, and dilute acidic solutions (Ref 27).

Compliant Coatings Issues and Future Trends

As the environmental consciousness of the world continues to increase, more efforts are being devoted to finding safe, compliant solutions to past, current, and future environmental problems.

Environmental Regulations and Hazardous Materials. One major factor affecting Naval aviation in recent years has been the Clean Air Act Amendment (CAAA) of 1990. This law significantly affects the type of materials and processes that will be approved for use in the future. In response to this situation, the Navy has expanded its efforts to reduce the amounts of hazardous materials generated from the cleaning, pretreating, plating, painting, and paint-removal processes used in both production and maintenance operations. The materials associated with these processes have been identified as major sources of hazardous waste by the Environmental Protection Agency (EPA) (Ref 28). Specifically, numerous research and development efforts have been established to address the environmental concerns with

organic coatings. These efforts have two main thrusts: the development of low-VOC coatings and the development of nontoxic inhibited coatings. The aim of low-VOC coatings is to meet environmental regulations, especially California's Air Quality Management Districts rules and the CAAA Control Techniques Guideline (CTG) for the aerospace industry (one of 174 source categories). The development of nontoxic inhibited coatings is concerned with eliminating toxic heavy metal pigments such as the lead, chromate, and cadmium compounds used in protective primers and topcoats.

Low-VOC versions of military aircraft primers and topcoats have already been developed that comply with the CAAA Aerospace CTG, based on waterborne and high-solids formulations. Figure 3 summarizes the VOC content of coatings over time. Some solvents are legally designated by the EPA as neither VOCs nor hazardous air pollutants (HAPs), such as 1,1,1-trichloroethane and acetone. These exempt solvents, while solving a VOC problem, frequently create an ozone-depleting chemical or safety problem and are no longer perceived as a potential solution.

Nonchromated Pretreatments. One of the main environmental thrusts in the pretreatment area is the total elimination of hexavalent chromium. This toxic material has been used widely in the aforementioned processes because of its outstanding performance as a corrosion inhibitor for aluminum. This property is of particular importance to the Navy, due to the extensive use

of aluminum in aircraft and weapon systems. Chromium (VI) is a known carcinogen, and regulatory agencies have recently enacted rules that limit or prohibit the use of this material, so alternatives are needed.

Nonchromated alkaline cleaners and nonchromated deoxidizers have been identified as acceptable alternatives to the current chromated processes. These materials have provided satisfactory performance in surface preparation and, in some cases, have been more cost-effective than their chromated predecessors.

Numerous nonchromated surface pretreatment materials have been investigated as replacements for the standard CCC. A summary of one such investigation is described in Ref 29. Three categories of alternatives have been studied in the Navy: inorganic nonchromated solutions, chromium (III)-base treatments, and sol-gel formulations. The first category includes solutions based on permanganate, cobalt amine, and ceric ion (among others) as the active corrosion-inhibiting agent. A Navy-developed chromium (III) treatment (Ref 30, 31) has shown corrosion-resistance and paint-adhesion properties comparable to CCCs in laboratory evaluations. Broader testing and in-service demonstrations of this technology are underway. Sol-gel formulations, although still in the initial phases of development, show promise. These materials are organic/inorganic polymers based on the hydrolysis and condensation of metal alkoxides. Figure 4 illustrates how, for example, silicon alkoxides (of general formula $\text{Si}(\text{OR})_4$)

can be reacted to form a barrier film strongly bonded to an oxidized aluminum surface. The chemistry of sol-gel films also allows a great deal of flexibility in modifying adhesive and other properties. While some of these alternatives have shown promise, a universal replacement for CCCs has not yet been achieved.

A self-contained pen has been approved by the Naval Air Systems Command and the Air Force for the repair and touch-up of CCCs. The pen significantly reduces waste related to conventional chromate wiping, because the formulation requires no rinsing and eliminates the need for brushes or rags. Nonchromate versions of the pen will be available for evaluation soon.

Chromic acid anodizing has been widely used in aerospace production and maintenance operations. Alternatives are sulfuric/boric acid anodize (SBAA) and thin-film sulfuric acid anodizing (TFSAA), as well as the standard type II sulfuric acid anodizing. General information on these processes can be obtained from Ref 32 to 35. Several Navy laboratory investigations are described in Ref 36 to 38. A full-scale successful demonstration of SBAA led to incorporation into specification MIL-A-8625 as type IC (sulfuric/boric acid anodize). Also, the laboratory studies have resulted in the definition of acceptable performance parameters for the TFSAA alternative that was incorporated into MIL-A-8625 as type IIB. The Navy is also investigating the performance of trivalent chromium pretreatment as a sealer for types IC, II, and IIB anodized aluminum.

Waterborne Technology. Water has long been used as a carrier for organic coatings. The polymers for these coatings are usually modified with hydrophilic groups and dispersed in water to form either solutions or emulsions. Most latex paints are based on thermoplastic resins that are suspended in water to form spherical particles. These particles, whether pigmented or neat, are usually covered with a thin layer of emulsifier to maintain a stable dispersion. When applied to a surface, these spheres coalesce into a continuous film as the water in the emulsion evaporates. This film formation mechanism tends to lead to longer drying times in humid environments. Effects of using water as the diluent include smoother surface finishes due to greater flowout, less overspray when using air application equipment (due to the higher density of water), and easier cleanup (usually accomplished with soap and water). Unfortunately, these coatings have some disadvantages. They are more sensitive to surface contamination, such as oils and greases. Also, these films tend to be porous, and their high affinity for water can lead to coating failure in high humidity.

Waterborne or water-reducible high-performance coatings are unique in the way that they employ resins that are usually not soluble in water. The resin exists in its own micellar phase (Fig. 5). Neutralized carboxylic groups and surfactants stabilize the particle. Excess amine and solvent distribute between the phases. Because the polymer exists in its own organic phase surrounded by water, the solvent distributes

Fig. 3 Summary of volatile organic content (VOC) levels in standard military coatings over time

Fig. 4 Formation of a silicon oxide barrier film to bond to an oxidized aluminum surface

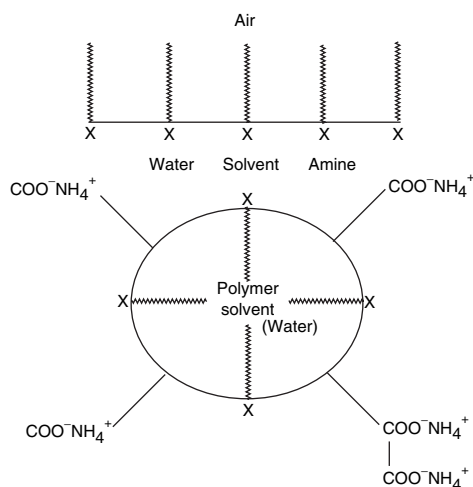

Fig. 5 Schematic diagram of a resin micelle (approximately 120 nm in diameter) in a waterborne coating

between the organic phase and the aqueous phase. This solvent, called the coalescing solvent or cosolvent, aids in film formation as the water evaporates by allowing binder and pigment particles to fuse in a continuous film (Ref 39). Because water is used as the primary liquid medium or as a diluent, formulations based on waterborne resins have much lower VOC levels than their solvent-borne counterparts. Recent advances in urethane and additive chemistries have shown that coatings approaching zero VOC are feasible (Ref 40).

One-component polyurethane dispersions have been in existence for some time. They generally consist of fully reacted polyurethane resins that are predominately thermoplastic. Because urethanes are not readily compatible with water, these systems are modified ionically and nonionically with hydrophilic groups to aid in the stability of the dispersions. After application, the films form by the coalescence of the long-chain urethanes. They tend to have lower cross-link densities and are not as chemically resistant as their solvent-borne counterparts.

Recently, researchers have been working with two-component waterborne polyurethane resins for high-performance coatings. One coating is based on an aliphatic polyol prepolymer and a polyisocyanate. The polyols are prereacted with diisocyanate resins and emulsifying agents to form a linear hydroxy-terminated prepolymer. The hydroxy-functional groups aid in the stabilization of the polyurethane dispersion. In addition, a water-dispersible polyisocyanate has been synthesized that has a preferential affinity for the polyol over the water competitor. The two components are mixed with an excess of isocyanate to form the final high-performance polyurethane product. Government laboratories and the commercial resin industry are investigating other variations on waterborne urethane chemistry. Coating manufacturers have begun to formulate finished products from this technology.

Zero-VOC Waterborne Topcoat. A zero-VOC topcoat was developed, based on a novel urethane chemistry that requires no cosolvent. Through manipulation of the polymer backbone chemistry and new rheological additives, a water-reducible polyurethane binder system contains virtually no organic solvents and emits no HAPs. The zero-VOC topcoat offers the potential for the Department of Defense (DoD) to go beyond environmental compliance in its painting operations. Successful implementation of this topcoat would result in the elimination of approximately 120 tons of VOCs per year, based on General Services Administration estimates of MIL-PRF-85285 topcoat usage throughout the DoD.

High-Solids Technology. Another method to attaining a reliable coating with lower VOCs is through the use of high-solids technology. Several paths to increase coating solids are possible. The first and most obvious reduction comes from simply lowering the solvent concentration. This approach shortens the pot life and significantly increases the resin viscosity when traditional raw materials are used. Also, the surface finish tends to be rougher from decreased flow characteristics. Another option is the use of reactive diluents. These materials are low-viscosity, low-molecular-weight compounds that act like a solvent for viscous resins. On curing, the reactive diluent becomes part of the polymer backbone and is not driven off as a VOC. Using low-molecular-weight resins can produce a high-solids coating with lower viscosity and better flowout. However, these materials tend to have short workable pot lives and lower flexibility when cured with traditional polyisocyanates. This lower flexibility is related to the increase in cross-link density resulting from the smaller backbone structures between functional groups. Using isocyanate-terminated prepolymers with a narrow molecular weight distribution as the

isocyanate source produces low-VOC coatings with good performance and processing characteristics. These prepolymers yield coatings with lower viscosity, shorter drying time, and longer pot life.

Another approach uses blocked polymers. These yield a longer pot life but tend to be less mobile, with slower reaction rates. Their decreased reactivity leads to long drying times, which is not desirable. In addition, high-boiling solvents can be used to replace conventional solvents. By incorporating these materials, the applied films retain the solvent longer, providing a smoother surface finish. However, this solvent retention leads to longer drying times and can cause the coating to sag. This characteristic has also produced a new phenomenon where sharp edges are exposed as the coating dries. Finally, solvent retention can result in film porosity, thus decreasing the chemical resistance.

Reactive diluents were used in the development of a low-VOC epoxy topcoat. For more than 30 years, epoxy/polyamide systems have been used as the standard binder for coatings requiring superior chemical and corrosion resistance. These coatings use an epoxy resin cured with a standard high-viscosity polyamide curing agent. The epoxy resin is based on the glycidyl ether of bisphenol-A given in Fig. 6. Here, the value of "n" is between 2 and 3, and the epoxide equivalent weight (molecular weight divided by functionality) is approximately 500. In formulations containing such systems, 40 to 50 vol% solvent is necessary to attain a sprayable viscosity, significantly contributing to VOCs. Two reactive diluents were explored: one was monofunctional and the other was difunctional. The number of epoxide groups contained in the molecule defines the functionality. The monofunctional cresyl glycidyl ether (CGE) and the difunctional neopentyl glycol diglycidyl ether (NGDE) are pictured in Fig. 7.

Fig. 6 Chemical structure of an epoxy resin based on the glycidyl ether of bisphenol-A.

Fig. 7 Chemical structures of the reactive diluents cresyl glycidyl ether (CGE) and neopentyl glycol diglycidyl ether (NGDE)

Fig. 8 Imine-isocyanate chemical reaction scheme. R, R', and R'' are repeating polymer chains. If the imine is aldimine, X is H; if it is ketimine, X is methyl or greater. In minor II, Y = X - 2H; for example, if X is CH₃, then Y is CH.

Fig. 9 Application of nonchromated waterborne epoxy primer to a T-2 aircraft at a naval air depot

Coatings prepared with CGE were unacceptable due to poor surface properties and possible fluid permeation through missing chemical cross links. Two successful formulations were prepared using NGDE, exhibiting superior performance and reducing VOC content to 60% of the standard epoxy topcoat. The reactive diluent effort was summarized in a technical report (Ref 41).

Low-molecular-weight resins based on aldimine chemistry were employed to develop low-VOC coatings. Aldimines are reaction partners for isocyanates. They replace the polyols in the reaction scheme. Aldimines have viscosities that are so low that the standard polyester polyol is more than 50 times more viscous. This allows for significantly less solvent usage to reach a sprayable viscosity.

Aldimine use in binder systems resulted from studies by a resin manufacturer using ketimine-isocyanate reactions to produce a major product, azetidinone, and some minor products, according to the schematic in Fig. 8. The minor products reacted further with the isocyanates, resulting in coatings that varied in stability and color. Substituting aldimines for the ketimines resulted in the formation of the cross-linked azetidinone polymer only (no minor products). It demonstrated good color and stability, with 100% retention of solids.

Pigmented formulations were prepared at VOC levels of approximately 200 g/L. These formulations failed to produce workable coatings even after numerous attempts. Each individual approach has deficiencies that present a challenging problem to resin manufacturers.

A combination of these technologies may have the greatest potential for success.

Low-VOC Technology Status. Numerous military and commercial specifications have been written to cover materials based on these technologies. High-performance, VOC-compliant primers, topcoats, and self-priming topcoats are required to have a maximum VOC content of 340, 420, and 420 g/L, respectively. Waterborne and high-solids technologies have allowed for the development of protective coatings that contain significantly reduced levels of VOC. Some of these are currently under evaluation both in the laboratory and in the field. At present, it does not appear that VOC levels of less than 200 g/L can be attained with high-solids technology (without exempt solvents) using present application methods. Novel waterborne resins suggest that the development of zero-VOC coatings, which meet existing requirements, is plausible.

Nontoxic Inhibitive Primer. Until recently, chromates were virtually the sole source for active corrosion inhibition in aircraft coatings due to their outstanding performance for nearly all metals in a range of environments. Nontoxic inhibitors that have been investigated as alternatives include phosphates, borates, molybdates, nitrates, and silicates. The mechanisms by which these inhibitors work are not thoroughly understood. Proposed mechanisms for zinc phosphate include the adsorption of ammonium ions, complex formation on the exposed surface, passivation through a phosphating process, and anodic/cathodic polarization. Phosphates, borates, and silicates are generally regarded as anodic passivators that reduce the rate of corrosion by increasing anodic polarization. Molybdates also have been classified as anodic inhibitors and are particularly effective at limiting pitting corrosion. At high concentrations, the oxidizing action of molybdates is the main factor behind its corrosion-inhibiting properties. Molybdate ions migrate into anodic areas and accumulate there. Although these pigments individually provide some level of corrosion inhibition, a one-for-one substitution for chromates did not result in equivalent corrosion protection. However, synergistic effects from combinations of some inhibitors provide nearly equivalent performance (Ref 35, 42-44).

A nonchromated waterborne primer was qualified to MIL-P-85582, class N, following

evaluation on several aircraft in the 1990s. There were no significant differences between the aircraft painted with the nonchromated primer and those painted at similar times with the standard primer. Application of the nonchromated primer is shown in Fig. 9.

In 1994, the Joint Group on Acquisition Pollution Prevention was chartered to coordinate joint service issues identified during the acquisition process. The group (now called Joint Group on Pollution Prevention) objectives are to reduce or eliminate hazardous materials, share technology, and avoid duplication of effort. Their product is a joint test protocol that establishes the critical requirements necessary to qualify alternative technologies. The Boeing Company organized a joint industry/government team to evaluate proprietary nonchromated epoxy primers for aircraft application. The Navy, Air Force, and National Defense Center for Environmental Excellence are participating.

Specifications MIL-PRF-23377 and MIL-PRF-85582 define the performance requirements for high-solids and waterborne primers, respectively. Paint manufacturers were asked to submit samples of nonchromated primers for evaluation under either of the specifications. Seven companies responded with 13 different products. The corrosion inhibitors were typically blends of several compounds described previously (phosphates, borates, molybdates). Primers were evaluated by the Navy for viscosity, pot life, drying time, surface finish, adhesion, flexibility, cure time, fluid resistance, corrosion resistance, and strippability. The nonchromated primers generally exhibited more corrosion in salt spray and filiform tests in comparison with control primers containing chromates. Only one candidate, a water-borne coating, met all of the qualification requirements.

Boeing conducted similar tests on these materials. They also included additional properties, such as sprayability, heat resistance, humidity resistance, thermal shock resistance, and compatibility with sealants, topcoats, and nondestructive inspection techniques. They confirmed the original results and recommended another waterborne primer as a second candidate for the service demonstration.

The demonstration included eight F/A-18 aircraft, two F-15 aircraft (wings only), an AV-8 aircraft, and several T-45 aircraft (touch-up applications). Either primer was applied to one side of each aircraft, and a standard chromated primer was applied to the other side. A MIL-PRF-85285 polyurethane topcoat was used over all of the primers.

The aircraft were based with operating squadrons at naval air stations in Beaufort, SC, Cecil Field and Tyndall Air Force Base, FL, and Lemoore, CA. Aircraft inspections over a 4 year period indicated no significant differences in corrosion resistance between the chromate and nonchromate primers. A joint test report for alternatives to chromate-containing primers for aircraft exterior mold-line skins was issued in February 1998. A later communication limited

implementation to scuff-sand/overcoat operations only (Ref 45).

Touch-Up Paints. One approach used to reduce VOC and hazardous waste from painting operations has been the development of self-contained touch-up paint applicators. Maintenance personnel must treat corrosion by removing oxidation products and loose paint, then repairing the original finish. Aircraft paints, such as MIL-P-23377 or MIL-PRF-85582 epoxy primer and MIL-PRF-85285 polyurethane topcoat, are supplied in two-component kits. Each component is taken from a quart or gallon can, mixed in a specific volume ratio, and sprayed with air-atomized equipment. Workers tend to use more material than necessary to assure sufficient coverage. Excess paints must be processed as a hazardous waste. Improper mixing ratios often yield poor film properties. Spray application requires respiratory protection for all personnel in the area. Usage beyond damaged areas adds weight to the aircraft, thereby reducing its speed and range.

A unique kit designed to store, mix, and apply small quantities of two-component paints has been developed. Approximately 10 cm³ (0.6 in.³) of the base and curing agent are contained in a clear plastic tube, separated by an impermeable barrier. When the barrier is displaced, the two components are easily mixed by shaking. A narrow brush on one end is used to dispense and apply the mixed material. A wider brush is also included. This kit, known as a Sempen, can be used to touch up areas of 0.1 to 0.2 m² (1 to 2 ft²) and is shown schematically in Fig. 10.

Fig. 10 Schematic diagram of the Sempen, a self-contained paint applicator pen

It has a number of advantages over spray application techniques using bulk materials:

- The small touch-up kit restricts maintenance personnel from mixing large quantities of paints that may be applied to excessive areas or disposed of as a hazardous waste.
- Brush application minimizes airborne concentrations of the toxic solvents, isocyanates, and the like in paints. Other personnel can work nearby without protective equipment.
- The individual components are premeasured to assure precise mixing and optimal properties.

A number of kits containing MIL-PRF-85582 epoxy primer or MIL-PRF-85285 polyurethane topcoat were supplied to operating squadrons for aircraft touchup. The materials were used during normal maintenance operations to repair painted surfaces that were cracked, chipped, or corroded. Personnel observed the ease of application, the appearance of the applied paint, and its durability over a 6 month period.

A one-component waterborne polyurethane topcoat has shown excellent performance. It is currently packaged in a 28 g (1 oz) jar with a brush applicator attached to the cap. A compatible one-component alkyd primer is also available in a similar container. A two-component high-solids polyurethane topcoat with unique properties has been developed. It is packaged in a 57 g (2 oz) jar with the curing agent in a plastic container underneath the cap. After mixing, it has an effective pot life of 7 days at ambient temperatures (30 days if refrigerated) but, when applied, will react with moisture in the air to dry within 2 h. The jar is designed for attachment to an aerosol sprayer. A number of two-component epoxy primers have also been packaged in the 57 g (2 oz) jars.

Maintenance personnel expend approximately 4 h per aircraft in the preparation, treatment, and cleanup associated with corrosion control. This time could be greatly reduced if they had access to all of the necessary materials in a single portable container. The container should include:

- Premoistened pads (such as Scotch-Brite, 3M Company) for surface preparation
- Wet and dry towelettes for cleaning
- Alodine Touch-N-Prep pens for chromate conversion coating
- Sempens and 28 g (1 oz) jars for brush application of paints
- Various 57 g (2 oz) jars for aerosol application of paints

Adhesive Films. Protective film technology has been used for specific applications in naval aviation for many years. One of the primary means of protecting aircraft radomes and leading edges from rain erosion is the use of elastomeric tapes. These tapes are flexible films bonded to painted surfaces with an attached adhesive. Recently, one manufacturer has developed an adhesive film aimed at replacing aircraft exterior

topcoats. This material, also known as applique?, provides a durable weather-resistant finish and is intended for application over a standard corrosion-resistant primer. The material consists of a polymeric layer and an adhesive layer, with a plastic backing over the adhesive. After removing the backing, the film is bonded to the primer in adjoining or overlapping sections. During application, only simple measuring and cutting tools are needed. The work can be done in any enclosed area with minimal training. Nearby personnel can perform installation and maintenance work at the same time, because no safety or environmental hazards are present.

Aircraft demonstrations of applique? technology have shown two significant problems. The pressure-sensitive acrylic adhesive is thermoplastic and tends to lose adhesion at higher temperatures, above 80 °C (180 °F). In addition, mechanical removal of the aged applique? for corrosion repair is difficult. The adhesive often leaves a sticky residue that must be stripped with solvent.

Electrodeposition Coatings and Powder Coatings. Electrodeposition of paint (e-coat) works on principles similar to plating. Charged paint particles are electrically plated to an oppositely charged conductive substrate. The object to be coated is dipped into the electrodeposition tank, and the current is turned on. During the operation, the paint coats every conductive surface (regardless of shape) with a uniform film whose thickness can be controlled very accurately. The paint film then insulates the substrate, preventing any further deposition of the coating. More details can be found in Ref 46 to 48. Because waterborne coatings are used in the e-coat process, VOCs are kept to a minimum. Also, no flammability hazards exist, and no elaborate ventilation systems are required, as with conventional spray techniques. A significant hazard does exist, however, with the electric power required. The tank area must be enclosed and have fail-safe controls. The technique is also limited to small conductive parts in aircraft applications. Also, temperatures approximately 150 °C (300 °F) or higher are required to cure these coatings.

Corrosion testing of e-coated panels revealed that, although it had superior adhesion, the coating was easily undercut by corrosion products at defects in the film. This phenomenon was due to the lack of corrosion inhibitor in the e-coat. The incorporation of such inhibitors in the tank resulted in coating bath instabilities. This fact, along with the costs and workload needed to maintain the process line, resulted in the decision not to implement e-coat for naval aviation purposes.

Powder coatings can be applied by a variety of methods, including fluidized bed, dip coating, and electrostatic spray. With electrostatic spray, as the powder passes the high-voltage electrode at the tip of the spray gun, it picks up the electrostatic charge and is attracted to grounded work. There, the powder adheres and will remain until fused and cured in an oven. More

Fig. 11 Powder coating spray booth at a naval air depot

detailed descriptions of powder coatings and application techniques can be found in Ref 47 and 49.

As with e-coats, the film thickness of powder coatings is controlled by the insulating effect of the powder film as it builds up on the substrate. Overspray is considerable, but it can be collected and reused, so losses are low. Because the material is a solid, there are no VOCs. However, an explosion hazard may exist due to the fine dust overspray. Therefore, careful grounding of the booth and equipment is required. A powder coating spray booth with an electrostatic spray gun is pictured in Fig. 11. Typically, parts are cured in a convection oven at 190 °C (375 °F) for 15 min.

Because of concerns affecting substrate properties such as temper at elevated temperatures, investigations continue for powder coatings with lower cure temperatures. Materials that cure between 120 and 150 °C (250 and 300 °F) are under test to determine if any serious property trade-offs will occur on lowering the cure temperature. Cure temperature affects cross-link density. It will, therefore, be necessary to address such properties as fluid resistance, corrosion resistance (limited barrier properties due to fewer cross links), and adhesion. There is also an investigation into the use of powder coatings on components that are not temperature sensitive.

Paint Application Equipment. As part of the CAAA aerospace guide, conventional spray application equipment will no longer be authorized for applying paints. This equipment has a transfer efficiency of approximately 28%. The types of paint application equipment authorized will be similar to those specified by California's regulations that require minimum transfer

efficiencies of 60 to 85% and maximum gun-tip air pressures of 0.007 MPa (10 psi). A number of alternative technologies have been proposed to meet this requirement. The only two spray application techniques authorized were electrostatic and high-volume, low-pressure (HVLP) spray guns. Both of these techniques have improved transfer efficiencies over conventional air spray. Roller, brush, dip, and other nonspray methods are also acceptable. Each of these techniques has its unique capabilities and limitations. Some methods can be used in combination (air-assisted airless with electrostatic) to yield even higher efficiencies. A study showed HVLP to be the most cost-effective, so this technology has been implemented at all naval air depots.

The method of cleaning spray equipment is also being regulated. The old solvent wash method, which generated large quantities of hazardous waste and was time-consuming, is being prohibited. An enclosed cleaning method, which captures the majority of the cleaning solvent, will be used. These enclosed cleaning operations take approximately one-fourth the time as the old method.

Nonchromated Sealants. The most effective inhibited sealants for fuel tanks were formulated from polysulfide polymers, soluble chromates, manganese dioxide curing agents, and other additives/fillers. Inhibited sealants are applied to prevent faying surface corrosion and dissimilar-metal corrosion and are also applied as corrosion-resistant coatings. Polythioether sealants have several advantages over polysulfide types, such as faster curing rates and a higher temperature range. Specification MIL-S-29574 has a type II category for a corrosion-inhibitive, fuel-resistant sealant.

A direct replacement for soluble chromate has not been found, so combinations of two or more compounds are necessary to make up new inhibitor packages for sealants. Inhibitors found to be effective replacements for chromates in paint primers and other corrosion-prevention materials were not directly transferable to sealants. Because of the interactions of the polymers, curing agents, adhesion promoters, fillers, and other ingredients, it was difficult and expensive to effectively formulate new inhibited nonchromated sealants with all the necessary properties. As a result, most of the reformulated inhibited sealants released by suppliers had limitations that needed to be resolved before even considering them for military use.

Military Coatings

Joseph T. Menke, U.S. Army

MILITARY COATINGS are as divergent as electrodeposited chromium plating in gun barrels and the visual camouflage paints applied to tactical equipment such as tanks, aircraft, and ships. The chromium plating in a gun barrel provides high-temperature (approximately 1650 °C, or 3000 °F) oxidation resistance, wear, and corrosion resistance. This plating is a single coating with multifunctional performance requirements. The paint system currently in use is a chemical agent resistant coating (CARC). This paint system consists of an epoxy primer and urethane topcoat and is multifunctional. The paint system provides weatherability (ultraviolet protection), mar resistance, chemical agent resistance, corrosion resistance, and spectral reflectance in addition to the visual camouflage. Spectral reflectance is the ability of paint to hide a piece of equipment from infrared (IR) sighting devices. Green high spectral reflectance coatings are used on ground equipment to match the color of trees and grass. Low spectral reflectance coatings of light blue, gray, and white are used to match the spectral properties of water and sky.

The many coatings used on Department of Defense (DoD) systems are categorized in

five major areas. These areas are obviously not all-inclusive but include:

- Electroplated coatings (applied with an electric current)
- Conversion coatings (applied without an electric current)
- Supplemental oils, waxes, lubricants
- Organic paint coatings
- Other finishes such as vacuum deposits (chemical and physical vapor deposition, ion vapor deposition, sputtering), mechanical plating, thermal spray coatings, and hot-dip coatings

Electroplating

Military coatings have many different performance applications. This article is limited to the corrosion performance of these coatings. Table 1 lists electroplated coatings. Typical direct current (dc) electroplated coatings used on steel surfaces include cadmium, zinc, chromium, nickel, copper, tin, lead, and aluminum. Anodizing and hardcoat are two processes used on aluminum surfaces that require dc electrical

current. One critical characteristic of most electroplated deposits that can affect corrosion resistance is coating thickness. The minimum thickness is generally a requirement that is specified in the technical data. Another aspect that is crucial to corrosion behavior is whether the coating is anodic or cathodic to the base metal. Of the electroplated coatings, only zinc and cadmium are anodic (sacrificial) to steel. The other electroplated coatings must be thick enough to create a barrier to chemical reactants to provide any level of corrosion resistance to the substrate metal. Figure 1 shows what can happen when the plating is a cathode with respect to the substrate metal and is not thick enough to be a barrier coating. The small-anode/large-cathode area ratio results in serious pitting of the underlying steel. Tin, lead, and aluminum coatings are an exception. They corrode readily in the salt-spray test, as the environment is aggressive enough to keep these coatings from being cathodes. In normal outdoor environments, tin, lead, and aluminum react with oxygen in the air and form a protective oxide on their surface. This metal oxide becomes a cathode with respect to iron and steel, and pitting corrosion can result with these coatings.

Commercial zinc plating for mild environments is 5 µm (0.2 mils) thick and will rarely pass 24 h in the salt-spray test before red rust appears. This thickness class service condition is considered "for indoor use" per ASTM B 633 (Ref 2) and is unsuitable for outdoor military

Table 1 Test requirements and time to failure of electrodeposited coatings

Coating	Thickness		Test minimum(a), h	Time to failure, h
	µm	mils		
Aluminum substrate				
Anodize	2.5–25	0.1–1	336	1500–7000
Hardcoat	51	2.0	...	100–500
Steel substrate				
Cadmium	5–13	0.2–0.5	...	200–600

tropical environments. A minimum 12 μm (0.5 mils) zinc coating class is suggested for military hardware by this standard, and the service condition is classified as severe. Material specifications must be explicit as to service condition when citing the standard and the thickness verified.

Anodize and hardcoat finishes on aluminum convert the aluminum metal to a thicker aluminum oxide film (relative to the "natural" or air-formed film). As shown in Fig. 2, aluminum oxide is a cathode with respect to aluminum, so pitting corrosion occurs at defects in the coating. Not sealing the hardcoat improves the wear resistance, but significantly compromises the corrosion resistance.

Accelerated Corrosion Tests. Table 1 summarizes the minimum results specified in technical procurement documents for accelerated corrosion tests and compares these to actual times to failure where the information is available for the coating process. The accelerated corrosion test method is the 5% salt spray per ASTM B 117 (Ref 1). This is the test procedure

by which the times to failure are determined. See the article "Cabinet Testing" in Volume 13A for much more on this test and similar tests.

Table 1 assists understanding the relative level of corrosion protection provided by various finishes under controlled and reproducible conditions. It is not a predictor of field performance. The minimum test requirement can be used as a process verification tool as it is what the process (properly applied) must meet to prove the process is under control. Process control test requirements are generally kept to a minimum so production acceptance times are as short as possible. The normal experience is that the time to failure is consistent under typical environmental conditions for systems exceeding the minimum requirement. The time to failure represents the actual performance of a coating.

A reference to automotive corrosion (Ref 3) has associated the 5% salt-spray test with expected performance in the field. Approximately 100 h exposure was determined to be equivalent to 1 year in service. This can be used only as a loose guide for comparison to estimate coating performance, because the variations in environmental factors, especially in the military environments, are so significant. Table 1 is consistent with experience that surfaces with 25 μm (1 mil) of chromium are generally rusty in a short period of time while surfaces with 76 μm (3 mils) of chromium are seldom found to be rusty. Table 1 also shows the beneficial effect of the chromate treatment on cadmium and zinc. The 96 h requirement to "white" corrosion product shows that the chromate treatment is protecting the plating that finally fails when the steel is exposed.

Conversion Coating

Conversion coatings used on military equipment include chromate conversion coatings on aluminum, cadmium, and zinc-base products

such as galvanize or zinc die castings. Electroless nickel, zinc and manganese phosphate, and black oxide are considered conversion coatings on steel. See the articles "Phosphate Conversion Coating" and "Chromate and Chromate-Free Conversion Coatings" in Volume 13A.

Black sulfide coatings on stainless steel and naphthanate coatings on wood are also conversion-coating processes. The black oxide and phosphate coatings are generally used with a supplemental treatment of oil, wax, or some other organic coating.

Table 2 lists the various conversion coatings that are applied by immersion without current. The same salt-spray test is applied. Using 100 h test exposure as a measure of 1 year in the field, it can be seen that conversion coatings by themselves do not provide significant corrosion protection. The exceptions to this are the black coating on 300 series stainless steel, the chromate on aluminum, and the electroless nickel on steel. These coatings are more permanent and do not require supplemental oil for improved corrosion resistance. The electroless nickel is a shiny coating and would not be considered for exterior surfaces on weapons unless it could be made nonreflective. The class 1 (C.1), class 2 (C.2), and class 4 (C.4) black coatings in Table 2 refer to coatings produced to MIL-DTL-13924 (Ref 4). The classes in MIL-DTL-13924 describe the different blackening processes that are available for different substrate materials.

Supplemental Oils

The supplemental oils add significantly to the salt-spray protection of phosphate and black oxide coatings. These oil coatings are, however, washed off easily in a rain or evaporated in the hot sun and must be constantly reapplied to maintain the corrosion resistance in the field. Figure 3 shows a weapon component that came back from the desert and was found to contain

Fig. 2 A section of a ring gear bearing from a howitzer in Hawaii. The gear is hardcoated aluminum and shows severe pitting at defects in the coating and at a defect from a scratch (bottom center). The coating is cathodic with respect to the scratch that is anodic.

Fig. 3 Rusting on a phosphated part after service in a desert environment. The phosphate coating had been blasted off by blowing sand leaving a bare metal surface. Phosphate coatings are specified on 75 to 90% of the parts for small arms.

almost no phosphate coating due to the abrasive action of blowing sand in the area. The phosphate coating is relatively soft, and the sand blasted the coating off the parts. Weapon parts became susceptible to rusting without the phosphate coating to hold the oil.

Supplemental oils provide a degree of corrosion protection that depends on the amount of rust preventive added to the formula and the film thickness of the oil. Levels of corrosion protection are shown in Table 3 and are normally determined on a sand or steel grit blasted, bare steel surface. The viscosity of these materials determines to some degree the thickness of the oil that will be retained on the surface. The MIL-PRF-32033 oil (Ref 5) is similar to the commercial product known as WD-40, and MIL-PRF-63460 (Ref 6) is the current field lubricant for small arms weapons. The film thickness of the oils in Table 3 is an approximation based on readings obtained with a wet film paint thickness tester. The MIL-PRF-3150 (Ref 7) and MIL-PRF-16173 (Ref 8) oils are primarily used for protecting metal parts inside various packaging schemes. They may be used over a phosphate coating or just over bare metal when used inside military packaging. Bare steel fasteners have a rust preventive oil specified on the drawings, but this protection may be lost prior to transportation to the field.

Paint Coatings

Paint coatings on military hardware should be considered painting systems that include surface preparation. The pretreatment for paint on

aluminum may be the chemical film or anodize coating. The pretreatment for paint on steel is usually a light zinc phosphate coating as shown in Table 4. The CARC systems have been in use since 1985 and consist of a pretreatment, epoxy primer, and urethane topcoat as shown in Fig. 4. The test, tactical, and material requirements for the CARC system are also shown, and it should be obvious that this is a coating system. The pretreatment ensures good adhesion of the primer and assists in providing a significant level of corrosion protection when used in combination with the primer. For example, the primer on bare steel provides about 50 h of salt-spray corrosion protection at the specified thickness. When that same primer is applied over a light zinc phosphate pretreatment, up to 1500 h of salt-spray corrosion protection can result. Incomplete coverage of the phosphate coating and a primer thickness below the minimum are the two most common causes of premature corrosion on CARC painted items. When topcoat is applied over the primer, additional corrosion protection is available. See the article "Organic Coatings and Linings," in Volume 13A.

As mentioned, the CARC topcoat is not applied solely for corrosion protection. The topcoat provides visual camouflage, resistance to chemical agents and decontaminating solutions, and exhibits spectral reflectance to escape detection by IR sensors (film or sights). The topcoat must exceed a minimum thickness of 46 μm (1.8 mils) to provide the spectral reflectance properties.

Level of Required Protection. Ammunition items using alkyl enamel paint may have parts requiring only 24 or 48 h of accelerated corro-

sion testing. On the other hand, the paint specification requires the zinc phosphate and paint to go 150 h in the 5% salt-spray test. Thus, a three- to sixfold reduction in the required life of the paint is acceptable according to the design of many ammunition items. The paint thickness used on the item is less than recommended elsewhere to meet other functional requirements, so the corrosion resistance for the item is reduced. For example, the lacquer paint on 20 mm projectiles is applied at 13 to 20 μm (0.5 to 0.8 mils) and the part has a 24 h salt-spray requirement. It is difficult to get corrosion resistance with very thin coatings. That is why ammunition items are often kept in sealed containers until the time they are used for practice or combat. With the one-coat ammunition paint, coverage with the phosphate coating is even more important since no primer is used to provide additional resistance to corrosion.

The levels of corrosion protection achieved with the different types of painted coatings are shown in Table 4. A dry film lubricant coating is applied like paint. The only difference is that the dry film coating has a pigment in it that provides lubrication rather than color. Numerous areas on the M16 rifle have a dry film lubricant providing different functions. On the exterior of the hard-coated aluminum lower receiver extension tube, the dry lubricant provides resistance to crevice corrosion. On the interior of the aluminum tube, the dry film coating prevents galvanic corrosion by the precipitation hardened 17-7 (UNS S17700) stainless steel spring. The dry film coating also lubricates the spring as it cycles in the tube. On the interior of the hardcoated aluminum upper receiver, the dry film coating lubricates the forward and back motion of the bolt. It is also important to note that the bake-on dry film

Table 3 Test requirements and time to failure of supplemental oils

Chromate + CARC primer(b)	15–20	0.6–0.8	2000	...

CARC, chemical agent resistant coating. (a) Test per ASTM B 117 (Ref 1). (b) Aluminum substrate

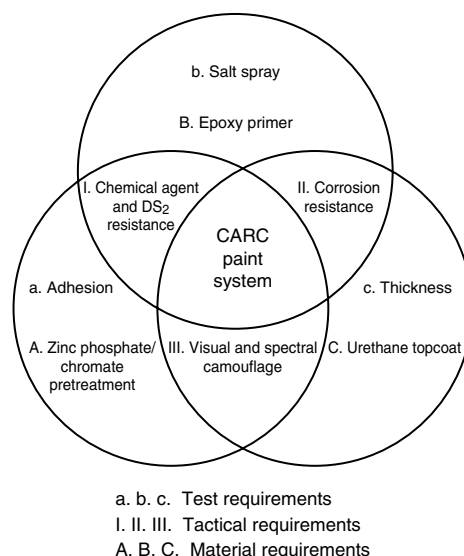

Fig. 4 A logical schematic of the relationship of materials (pretreatment, primer, and topcoat) used for chemical agent resistant coating (CARC) paint systems with the tactical and test requirements. DS₂ is decontamination solution.

lubricant is chemical agent and decontamination solution resistant, while the air-cure material is not resistant to chemical agents. It is apparent from the last entry in Table 4 that, when the pretreatment provides significant corrosion resistance by itself, the overall corrosion resistance of pretreatment and paint system shows significant improvement.

Other Finishes

The final category of finishes used on military equipment include deposits applied in a vacuum, mechanical plating, thermal spray, and hot-dip coatings. See the articles "Continuous Hot Dip Coatings," "Batch Process Hot Dip Galvanizing," "Thermal Spray Coatings," and "CVD and PVD Coatings" in Volume 13A.

Cadmium and ion vapor deposited (IVD) aluminum are two production coatings applied under vacuum conditions. Zinc, tin, aluminum, and lead-tin coatings are typically applied by the hot-dip (molten metal) process. Mechanically deposited coatings include cadmium, tin-cadmium, tin, and zinc. Thermal spray coatings include aluminum and zinc. The levels of corrosion protection achieved in this final category are shown in Table 5. One of the interesting aspects of thin aluminum coatings is its ability to protect steel in the salt-spray test but not in normal outdoor environments. In the salt-spray test (a very aggressive electrolyte), the aluminum remains an anode and protects the steel, as would be expected from looking at a galvanic

series chart. However, a normal outdoor environment is not as aggressive and an oxide coating forms on the aluminum surface. This oxide coating changes the aluminum from an anode to a cathode with respect to steel, and rusting begins at defects or voids in the aluminum coating. Thus, the accelerated test information can be misleading when the test does not represent what is happening in the outdoor environment. Thermal spray coatings of aluminum 127 to 254 μm (5 to 10 mils) thickness are essentially barrier coatings and not sacrificial coatings. These coatings have been used on the decks of ships and have performed very well. Vacuum-deposited coatings are used to minimize the problems associated with hydrogen embrittlement that may be encountered during electroplating operation. Hydrogen-induced stress-corrosion cracking is a problem with electroplated coatings used on high-strength fasteners. Hydrogen generated during acid pickling and electroplating can enter the steel and cause embrittlement. If the hydrogen is not removed, it can cause premature failure in the field. Vacuum-deposited coatings do not generate hydrogen in the plating process and, as such, are the preferred process for critical coating applications on high-strength steel parts.

In summary, coatings in the five areas represent a selection of processes available for corrosion protection in military environments. Process tests ensure that the minimum requirements are met before the parts leave the manufacturer's plant. The coatings can provide the needed corrosion protection only when the

parts are properly designed, the coating system is selected to meet the specified service requirements, and the processing has been controlled.

U.S. Navy Aircraft Corrosion

John E. Benfer, Naval Air Systems Command, Research and Engineering Sciences Department

U.S. NAVY AIRCRAFT experience severe conditions in operational service that include: aircraft carrier based deployment and carrier landing (Fig. 1), maritime shore based deployment, and near sea level maritime missions. The mechanical loads experienced during flight have led to the development and selection of aerospace alloy systems with a primary emphasis on high strength, stiffness, and low specific gravity. Trade-offs associated with corrosion-resistance properties occurred during the initial concept and design phases of these aircraft during acquisition processes of the 1960s through early 1980s. As a result, currently fielded aircraft weapon systems experience high life-cycle costs due to increased maintenance and decreased component/system reliability from degradation associated with corrosion.

Aircraft structures begin to deteriorate from the time they leave the manufacturing facility, primarily due to mechanical and corrosion damage. Abrasion, wear, and fatigue mechanisms contribute to the mechanical damage phenomena and are affected by aircraft design and service loads. Corrosion damage in the form of pitting, exfoliation, and uniform metal loss phenomena via electrochemical oxidation is controlled by the aircraft design, the materials selected, and the operating environment. Interactions between mechanical and corrosion mechanisms can also occur resulting in corrosion fatigue, stress corrosion cracking, and fretting phenomena.

As an aircraft ages, the effects of corrosion become more severe due to cumulative damage. If corrosion and corrosion-damaged areas are not detected early and mitigated, a serious hazard to the structural integrity of the aircraft may result.

Fig. 1 Navy aircraft making carrier landing

Therefore, it is critical to identify and employ the latest technologies associated with cleaning, washing, inspection, treatment, and corrosion prevention into the maintenance cycles of all navy platforms. Failure to address corrosion control throughout the life cycle of the aircraft increases maintenance costs and reduces aircraft life, thus affecting the military's ability to achieve their operational commitment.

Environment

The operational environments of U.S. Navy aircraft vary widely, and therefore corrosion rates can also vary considerably. Geographic location affects temperature, humidity, and air quality of ground based squadrons. The severe conditions associated with aircraft carrier based squadrons (Fig. 2) create the most challenging corrosion-control issues within aviation. While flight conditions and landing and takeoff events are in themselves very severe operational environments, most navy aircraft spend a considerable amount of time on the ground. Therefore, the ground environment is an important consideration to overall corrosion-prevention strategies. It has been found through corrosion monitoring of military sites and in-flight environments that the above-deck aircraft carrier environment is three to four times more severe than any land based environment.

Atmospheric environments can be classified in three basic corrosion categories to represent a

Fig. 2 U.S. Navy aircraft carrier deck illustrating operating environment of carrier based squadrons

generic rating for the degree of corrosiveness. Climate, industry, and location form a basis of this generic rating to include the effects of temperature, humidity, pollution/impurities, pH, and salts. These categories can be reduced to many subcategories; however, most common descriptions, organized based on corrosion rate, are shown in Table 1.

Temperature directly affects the kinetics of corrosion rates. Higher temperatures also cause corrosive solutions to dry, which results in a higher concentration of impurities on aircraft surfaces. Humidity levels above 60% lead to formation of thin aqueous electrolyte films capable of creating local corrosion-reaction cells with increased corrosion rates. Cyclical occurrence of condensate contaminated with dissolved salts and atmospheric impurities followed by dry-off in high-temperature areas concentrates impurities and creates one of the most common mechanisms associated with general corrosion within the naval aviation maintenance community.

Aircraft Alloys

Corrosion-resistance properties at times are sacrificed to achieve the previously mentioned mechanical design requirements, formability, and cost, during development of aircraft weapon systems. The most widely used materials in airframe structures and components are aluminum, steel, titanium, and magnesium alloy systems.

Aluminum Alloys. With the exception of magnesium, aluminum by its position in the electrochemical series is thermodynamically one of the most reactive metals used in naval aircraft. In service, it is often resistant to corrosion because it is protected by oxide films that rapidly

Table 1 General corrosion rates associated with geographic location

Rate of corrosion	Type of atmosphere		
	Climate	Amount of industry	Location
High	Tropical	Industrial	Marine
Moderate	Temperate	Suburban	Inshore
Low	Arctic	Rural	Inland

form in atmospheric environments. This passive film, however, can result in localized pitting corrosion at defect areas within the oxides. Aerated halide solutions (e.g., chloride from salts) commonly result in pitting corrosion damage of aluminum alloys. This environment commonly occurs with maritime aircraft programs and aircraft deployed to aircraft carriers.

The corrosion resistance of aluminum is strongly influenced by its chemical composition as a consequence of impurities and alloying elements. Principal alloying elements include zinc, magnesium, silicon, copper, and manganese. Wrought heat treatable aluminum alloys are the most widely used in airframe construction with many different compositions and heat treatments to achieve final properties. The most important of these alloy systems are the 2xxx series (Al-Cu-Mg) and the 7xxx series (Al-Zn-Mg). These alloys are strengthened by precipitation-hardening treatments that involve heat treatment, rapid quenching, and natural aging at room temperature or artificial aging at elevated temperature.

2xxx series alloys have strong electrochemical effects due to the presence of copper. Variations of copper concentrations (heterogeneous segregation) in solid solution lead to variations in electrode potentials and thus local galvanic cells. Copper also has the tendency during electrochemical corrosion reactions to replate on aluminum surfaces and form small cathodic sites causing additional local galvanic cells. These alloys are susceptible to pitting and stress corrosion.

7xxx series alloys contain zinc and magnesium and include a great number of alloys that also contain copper (e.g., Al 7075). These alloys are strengthened by precipitation of solute-rich zones and are among the highest-strength materials available on the basis of strength-to-weight ratios. 7xxx series alloys are also more resistant to general corrosion than 2xxx series alloys. However, they are susceptible to stress-corrosion cracking and exfoliation corrosion. 7xxx series alloys with higher copper contents allow for higher aging temperatures without excessive loss of strength. The T7 heat treatment have been developed to improve resistance to exfoliation and stress-corrosion cracking.

Aluminum cladding is used on sheet products, such as fuselage skins, fuel tank divider webs, and other components. Cladding alloys are selected to be anodic to the core alloy and provide cathodic protection to the core. Cladding materials are metallurgically bonded via rolling processes to the core material. Corrosion progressing through the cladding will progress to the core interface and spread laterally and prevent perforation of the core material. Figure 3 illustrates the protective nature of aluminum cladding and the associated resistance to pitting corrosion of the core material.

Steel Alloys. Carbon and low-alloy steels used in airframe structures and components vary in susceptibility to corrosion and the modes of corrosive attack due to variations in composition

and heat treatment. Carbon steels used in low-strength applications are prone to uniform corrosion in atmospheric conditions. Low-alloy steels (Ni-Cr-Mo) used in high-strength applications can be less susceptible to atmospheric corrosion as compared with carbon steel alloys. Low-alloy steels, however, are more prone to pitting, stress-corrosion cracking, and hydrogen embrittlement. Carbon and low-alloy steels require the application of inorganic coatings (e.g., ion vapor deposited aluminum or electroplated cadmium) and/or organic coatings (e.g., epoxy, polysulfide, or polyurethane) to resist corrosion in the environments associated with naval aviation.

Stainless steel alloys form a protective oxide film that provides excellent resistance to uniform corrosion and include austenitic, martensitic, and age-hardening groupings. The passive film formation on stainless steels leads these alloys to be very susceptible to localized pitting and crevice corrosion. Segregation of alloying elements due to improper heat treatment or thermal exposure can promote intergranular corrosion. Stress-corrosion cracking can occur in chloride environments, especially when aircraft are carrier based and exposed to cyclic wetting and drying of chloride-containing seawater.

Austenitic stainless steel (300 series) provides the greatest resistance to general corrosion due to the presence of chromium and nickel alloying elements. These alloys are not strengthened by heat treating and are used predominantly in low-strength applications. Martensitic stainless steel (400 series) are less resistant to general corrosion than the austenitic stainless steels due to compositional changes that provide increased strength through quench-and-temper heat treatments. Age-hardening stainless steels are hardenable through precipitation heat treatments and provide high strength combined with atmospheric and general corrosion resistance approaching the austenitic stainless steel alloys.

Titanium and titanium alloys provide low density, high strength-to-weight ratios, and high corrosion resistance. The excellent corrosion resistance of titanium is due to the formation of a protective titanium oxide film during atmospheric exposure. Titanium is cathodic to most alloys used in aviation with the exception of some passive stainless steel alloys. As a result, protective measures should be in place at areas in which titanium is coupled to dissimilar metal airframe structures.

Titanium alloys have excellent resistance to pitting, galvanic corrosion, crevice corrosion, erosion-corrosion, and corrosion fatigue in marine environments. However, many alloys are susceptible to stress-corrosion cracking in aqueous chloride environments. Liquids such as methanol, ethanol, and ethylene glycol have also been found to cause cracking. Titanium alloys are also highly susceptible to the reduction of fatigue life by fretting at interfaces between other metals.

Magnesium is the most corrosion-prone and reactive material used in the manufacturing of aircraft structural components. Unalloyed magnesium is not extensively used for structural purposes and, therefore, is alloyed with additions of aluminum, lithium, zinc, rhenium, thorium, and silver. Minor additions of cerium, manganese, and zirconium may also be used. These elements are selected to enhance response to strengthening treatments and improve corrosion resistance. Elements such as iron, nickel, cobalt, and copper have severely deleterious effects on the corrosion resistance of magnesium. They are typically controlled at low impurity tolerance limits to reduce this effect.

Aluminum and zinc are the most widely used alloying elements in magnesium because they have high solubility and give rise to some of the highest strengths. Magnesium alloy AZ91 (Mg-9Al-1Zn) is a commonly used cast alloy that exhibits good weldability and low porosity. All magnesium alloys are subject to general and pitting corrosion when exposed to natural environments and must be surface treated and protected. Breakdowns in corrosion-protection systems result in rapid corrosion of the magnesium alloys, especially where galvanic couples are present, that is, steel inserts, fasteners, and mounting areas. This is especially prevalent within maritime environments associated with naval aviation.

Aircraft Inspection

Aircraft must be inspected for signs of corrosion and to ascertain the condition of protective coatings used for corrosion prevention. Prior to flight, inspections involve visual checks of airframe surfaces and operational checks of engines and flight controls. Detailed maintenance inspections are usually performed at predetermined intervals based on flight hours or time. These intervals are set using prior history of corrosion-prone areas with highly susceptible

Fig. 3 Aluminum laminate. Al 7072 aluminum cladding providing corrosion protection of Al 7075-T6 core. Note lateral spread of corrosion at clad layer to prevent through wall failure of a P-3 fuel tank divider web. Courtesy of K. Himmelheber, Naval Aviation Depot—Jacksonville

and critical areas being inspected more frequently than areas of low susceptibility and criticality.

Visual inspections are carried out on external surfaces and internal structures visible through quick access doors and panels by direct line of sight or through the use of inspection mirrors. Aided visual inspections are carried out less frequently and incorporate more thorough techniques to include magnifiers and fiber-optic probes. Special inspections are carried out on known problem areas using additional non-destructive techniques to include x-ray, magnetic particle, eddy current, ultrasonic, and liquid penetrant inspections. These techniques provide more detailed inspection results and at times require either partial or complete disassembly of components to be evaluated.

Nondestructive inspections are designed and timed to detect all forms of structural deterioration at early stages to prevent in-service component failure. The first appearance of corrosion on unpainted surfaces may be in the form of small deposits or spots. On painted surfaces this appears as small blisters within the coating that vary in shape from round and circular to thin and filamentlike. Common areas include skin areas around fasteners, seams, lap joints, butt joints, and crevices that collect debris and have long times of wetness. Areas exposed to battery electrolytes, engine exhaust, and gunfire gases are also prone to corrosion. The form and location of corrosion on aircraft materials have characteristics as indicated in Tables 2 and 3. Examples of aircraft corrosion damage are shown in subsequent sections of this article.

Prevention and Corrosion Control

The primary consideration in the design and construction of naval aircraft is the balancing of safety, affordability, and environmental needs with operational and mission requirements. Aircraft are also required to perform reliably, have minimum maintenance requirements, and acceptable degradation rates to achieve maximum service life. Deterioration due to all anticipated forms of corrosion (uniform, pitting,

galvanic, crevice, exfoliation, stress-corrosion cracking, corrosion fatigue, fretting, hydrogen embrittlement, weathering, and fungus growth) must be managed through the selection of suitable materials and processing methods and maintenance.

Materials selection and processing method choices to obtain the best value with regard to the control and mitigation of corrosion requires attention at the component, assembly, and system level. The design should also control the exposure to corrosive contaminants through the use of appropriate manufacturing processes and design geometries that prevent the collection and entrapment of contaminants. The proper selection of materials and use of design in conjunction with the application of protective coatings is the optimum approach to maximize corrosion performance. More can be done during design to improve corrosion performance than at any other time of product life cycle.

Cleaning. Aircraft cleaning is the first step in preventing corrosion. Cleaning requires a knowledge of the materials and methods needed to remove corrosive contaminants and fluids that tend to retain contaminants. Aircraft are cleaned on a regular basis (typically every 14 days while ashore and every 7 days while at sea) in order to:

- Prevent corrosion by removing salt deposits, other corrosive soils, and electrolytes
- Allow a thorough inspection to identify corrosion and corrosion damage

More frequent and thorough cleaning is necessary for a particular aircraft model that experiences:

- Excessive exhaust or gun blast soil that accumulates at impingement areas
- Damaged paint systems including peeling, cracking, flaking, or softening
- Leakage of oil, coolant, and hydraulic fluids
- Exposure to salt spray, saltwater, and other corrosive materials

Cleaning compounds and detergents used for washing aircraft work by dissolving soluble soils, emulsifying oily soils, and suspending solid soils. Moderately alkaline cleaners of pH < 10 are used and procured under MIL-PRF-

85570 (Ref 1). This military specification contains a variety of detergent types that include:

- Type I—General-purpose aromatic solvent base
- Type II—General-purpose, nonsolvent base
- Type III—Abrasive spot cleaner
- Type IV—Rubberized spot cleaner
- Type V—Gel-type wheel well degreaser, low solvent base

Postcleaning procedures are required after aircraft washing to ensure that entrapped water is removed/drained and that lubricants are reapplied to minimize wash-induced corrosion effects. Postcleaning procedures are:

1. Remove covers from vents, tubes, air ducts, and so forth.
2. Remove tape from openings sealed prior to washing.
3. Clean all drain holes to allow proper drainage.
4. Inspect all water accumulation areas and drain/dry as required.
5. Lubricate in accordance with maintenance manuals to displace remaining moisture/water and allow proper operation of applicable system.

Lubrication has multiple purposes: preventing wear between moving parts, filling air spaces, displacing water, and providing a barrier against corrosive media. Conventional lubricants consist of a variety of grease-type materials that can be applied by lever or pressure-type grease guns, aerosol spray, squirt can, or applied by hand or brush. Solid-film lubricants are used where conventional lubricants are difficult to apply, or become contaminated with wear products or moisture. Typical applications are for flap tracks, hinges, turnbuckles, and cargo latches.

Corrosion-preventive compounds (CPCs) are mixtures of special additives in petroleum, solvent, lanolin, or wax bases and are used to temporarily protect metallic aircraft parts and components. They function by preventing corrosive materials from contacting and corroding bare metal surfaces. Many of these compounds also displace water, seawater, and other

Table 2 Appearance of corrosion product

Alloy system	Type and susceptibility of corrosion	Appearance of corrosion product
Aluminum	Pitting, intergranular, and exfoliation	White or gray powder
Titanium	Highly corrosion resistant. Extended contact with chlorinated solvents may result in degradation of structural properties.	No visible corrosion products
Magnesium	Highly susceptible to pitting	White powder, snowlike mounds, and white spots on surface
Low-alloy steels	Surface oxidation, pitting, and stress-corrosion cracking	Reddish-brown oxide (rust)
Corrosion-resistant steel (CRES)	Highly resistant to general corrosion. Susceptible to pitting, intergranular corrosion, and stress-corrosion cracking	Corrosion evident by rough surface with possible red, brown, or black stains
Nickel	Good corrosion resistance. Sometimes susceptible to pitting	Green powdery deposit
Copper	Surface and intergranular corrosion	Blue or blue-green powder deposit
Cadmium (sacrificial electroplated coating)	Good corrosion resistance. Will protect steel from attack	White-gray powdery product
Chromium (wear-resistant electroplated coatings)	Susceptible to pitting in chloride environments	No corrosion product. Steel corrosion may be visible at coating defects

Table 3 Typical locations of corrosion on aircraft

Location	Type of corrosion	Comments	Detection method(a)	Maintenance repairs(b)
Exterior fuselage				
Skin	Surface, pitting, and filiform	Paint failure around rivets and fasteners	V	RBR. Install patches if beyond negligible damage limit.
Doors	Surface, intergranular, and exfoliation	Paint failure induced by door use	V	RBR. Install patches if beyond negligible damage limit.
Access panels and attach area	Surface, intergranular, and exfoliation	Paint failure induced by maintenance, moisture intrusion	V	RBR. BAS
Nose section				
Nose radome latches	Galvanic (steel fasteners in aluminum structures) and intergranular	Paint failure induced by usage	V	RBR. BAS. Item replaced if damage is extensive
Nose wheel well	Galvanic (steel fasteners in aluminum structures) and intergranular	Paint failure from door actuation, moisture intrusion	V	RBR. Item replaced if damage is extensive
Windshield frames	Surface, intergranular, and exfoliation	Moisture intrusion from sealant failure	V	RBR. Install patches if beyond negligible damage limit. Item replaced if damage is extensive
Battery and vent area	Chemical attack	Battery failure	V	BAS.
Bulkheads	Surface and intergranular	Paint damaged by maintenance	V	RBR. Install patches if beyond negligible damage limit.
Heat-exchanger door	Intergranular and exfoliation	Moisture intrusion	V	RBR. BAS. Item replaced if damage is extensive
Control cables	Surface	...	V	Item replaced if damage is extensive
Forebody				
Longerons, frames, and stringers	Surface and intergranular	Moisture trapped in insulation	V	RBR. BAS. Item replaced if damage is extensive
Floor structures, lavatory floor, and substructure	Surface, chemical attack, and exfoliation	Paint failure from usage and spills	V	RBR. Install patches if beyond negligible damage limit. BAS. Item replaced if damage is extensive
Bomb bay	Galvanic (steel fasteners in aluminum structures) and surface	Paint failure by door operation and stores loading	V	RBR. BAS. Item replaced if damage is extensive
Midbody				
Floor structures	Surface, chemical attack, and exfoliation	Paint failure from usage and spills	V	RBR. Install patches if beyond negligible damage limit. BAS. Item replaced if damage is extensive
Fuselage to wing fitting	Stress-corrosion cracking	Paint failure due to wing flex and moisture entrapment	...	RBR. Item replaced if damage is extensive. Extensive repair
Aftbody				
Entry ladder and towage area	Surface and intergranular	Paint failure from usage	V	RBR. Item replaced if damage is extensive
Floor structures	Surface, chemical attack, and exfoliation	Paint failure from usage and spills	V	RBR. Install patches if beyond negligible damage limit. BAS. Item replaced if damage is extensive
Empennage—vertical and horizontal stabilizer				
Planks, spar caps, and webs	Intergranular and stress-corrosion cracking	Paint and sealant failure from airframe flex and vibration in flight	V, U	BAS. Item replacement if damage is extensive. Requires access holes cut and panel to be manufactured
Control surfaces and trim tabs	Surface and exfoliation between inner and outer skins	Moisture entrapment, paint and sealant failure from airframe flex and vibration in flight	V, U	BAS. Item replacement if damage is extensive. Cut out extensive damaged structure and insert a replacement section.
Latches	Galvanic (steel fasteners in aluminum structures) and intergranular	Paint failure induced by usage	V	RBR. BAS. Item replaced if damage is extensive
Rudder upper torque tube attach fitting and lower rib to beam fitting	Surface, exfoliation, and dissimilar metal galvanic (steel fasteners in aluminum structures)	Moisture entrapment, paint failure from flex, and vibration in flight	V, U	RBR. Item replaced if damage is extensive
Wing assembly				
Forward spar caps and web assembly	Intergranular, exfoliation, and stress-corrosion cracking	Inspection difficult, requires removal of leading edges	V or fuel leaks	RBR. BAS. Extensive repair. Cut out extensively damaged structure and insert a replacement section.
Aft spar caps and web assemblies	Intergranular, exfoliation, and stress-corrosion cracking	...	V or fuel leaks, confirmed U	RBR. BAS. Extensive repair. Cut out extensively damaged structure and insert a replacement section.
Upper and lower planks	Intergranular, exfoliation, and stress-corrosion cracking	...	V or fuel leaks, confirmed U	RBR. BAS. Extensive repair. Cut out extensively damaged structure and insert a replacement section.
Fillet panel and dome nut holes	Surface intergranular and galvanic (steel fasteners/nutplate in aluminum structures)	Paint failure induced by airframe flex and moisture intrusion		RBR. BAS.
Access door lands	Surface, intergranular, and stress-corrosion cracking	Paint failure induced by maintenance	V	RBR. BAS.
Mooring fitting attach and stores fitting holes	Surface, exfoliation, and galvanic (steel fasteners in aluminum structures)	Mooring fitting installed for extended periods of time, moisture entrapment	V	RBR. BAS. Cut out extensively damaged structure and insert a replacement section.
Flapwell panels	Surface and exfoliation between inner and outer skins	Moisture entrapment, paint and sealant failure from airframe flex and vibration in flight	V	BAS. Item replacement if damage is extensive. Cut out extensively damaged structure and insert a replacement section.

(a) V, visual inspection; U ultrasonic nondestructive inspection. (b) RBR, remove corrosion product by blending and repaint; BAS, install backup angles and plates to restore strength

Table 3 (continued)

Location	Type of corrosion	Comments	Detection method(a)	Maintenance repairs(b)
Wing assembly (continued)				
Trailing edge	Surface and exfoliation between inner and outer skins	Moisture entrapment, paint and sealant failure from airframe flex and vibration in flight	V	BAS. Item replacement if damage is extensive. Cut out extensively damaged structure and insert a replacement section.
Nacelles				
Main wheel wells	Galvanic (steel fasteners in aluminum structures), intergranular	Paint failure from door actuation	V	RBR. Item replaced if damage is extensive
Nacelle attach angles	Intergranular	Paint failure from vibration	V	RBR. Item replaced if damage is extensive. Cut out extensively damaged structure and insert a replacement section.
Gearbox supports	Surface and intergranular	Moisture intrusion	V	RBR. Item replaced if damage is extensive
Lower longerons	Galvanic (aluminum extrusion with stainless steel webs), intergranular	Moisture intrusion	V	RBR. Item replaced if damage is extensive. Cut out extensively damaged structure and insert a replacement section.

(a) V, visual inspection; U ultrasonic nondestructive inspection. (b) RBR, remove corrosion product by blending and repaint; BAS, install backup angles and plates to restore strength

contaminants from the surfaces to be protected. Some CPCs also provide lubrication in addition to corrosion protection. CPCs range in appearance from thick black barrier coatings (MIL-PRF-16173, grade 1) (Ref 2) to light lubricating oils (MIL-PRF-32033) (Ref 3). CPCs can be categorized as:

- Water displacing
- Non-water-displacing
- Lubricating
- Hard film
- Soft film
- Thin film

Selection of these materials is based on specific functional requirements of the aircraft component. Thick heavy coatings of CPC materials provide the best corrosion protection and are longer lasting, but are difficult to remove. Hard films provide excellent barrier protection, but are prone to chipping or cracking under stress and vibration. Thin films provide lubricating properties, but require more frequent applications. Under certain circumstances, CPCs can be applied as a system with a thin water-displacing material applied as an initial layer and then followed with a thicker hard film for improved durability.

Corrosion removal involves cleaning all visible corrosion products from a damaged area. The type of process will vary based on the type of surface involved, the size of the area, and the degree of corrosion found. Corrosion should always be removed using the mildest technique available to ensure that additional damage is not incurred during treatment. Tools for the removal of corrosion include nonpowered abrasive mats, abrasive cloth, abrasive paper, metallic wool, wire brushes, pumice, and scrapers. Powered methods include pneumatic sanders, flap brushes, flap wheels, rotary files, and abrasive blasting. Other factors to consider are:

- Before attempting corrosion removal, surfaces must be cleaned and stripped of paint.
- Adjacent components and parts must be protected from damage that could be induced during the corrosion-removal process.

- Allowable repair limits must be identified. If the corrosion-removal process cannot be performed without exceeding repair limits, the component will require replacement.

Material compatibility must be considered for any corrosion-removal process to ensure that additional corrosion damage does not occur due to galvanic effects associated with cross-contamination. For mechanical removal, like materials should be used whenever possible. Aluminum wool (not steel wool) should be used to remove general corrosion products from aluminum surfaces, while brass wire brushes should be used for copper alloys. Abrasives for sanding and blending are typically manufactured from aluminum oxide or silicon carbide. Blast media are supplied as silicon dioxide (glass) beads or aluminum oxide. The more aggressive aluminum oxide blast media are typically used on ferrous alloys.

Critical structures require additional treatment following corrosion removal. Pitting damage on critical structures requires complete blending to prevent stress risers that may initiate fatigue or stress-corrosion cracks. Blending is typically performed mechanically by “dishing” out the process areas to a diameter 20 times the depth of corrosion pitting. Blending of pitting damage is not routinely performed on noncritical structures.

Surface Treatment. Chemical surface treatments are performed to modify or convert the surface of aluminum and magnesium aerospace alloy systems and produce a surface layer with greater corrosion resistance and improved adhesion properties, through the formation of protective oxides or chromate films. These treatments typically involve the use of chromic acid or chromium salts for magnesium and aluminum alloys. However, nonchromate-containing products are under development to ensure compliance with future environmental and safety regulatory requirements. When exposed to water/moisture, corrosion inhibitors can leach out, providing a self-healing property when the base alloy is exposed by scratching or abrasion. In addition to improved corrosion

performance, chemical surface treatments provide improved surface adhesion of subsequently applied organic coating systems through a change in surface morphology and chemistry at the microscopic level that increases the surface area and number of bonding sites for subsequent coatings.

Thicker, harder, and more corrosion-resistant films can also be produced on aluminum and magnesium alloys through a process of electrolytic oxidation. These anodic (anodized) coatings are formed by oxidation in an electrolyte forming a thin, continuous oxide barrier film. Thickness is controlled and regulated by oxidation time and processing conditions. Anodic coatings contain microscopic pores that are sealed to enhance corrosion resistance, typically with a chromate solution. Anodic coatings are occasionally used to eliminate galling at faying surfaces, to retain lubricating fluids or greases, and to provide a surface for bonding adhesives and organic coating systems.

Anodic coatings can lead to the lowering of fatigue strength properties for metals. Such an effect can be reduced through peening processes that produce compressive stress at the metal surface or through the reduction of oxide thickness (thin-film anodizing). For certain fatigue-sensitive materials or components, chemical conversion coatings are generally used as an alternative to anodic coatings.

The performance requirements for control of conversion coatings and anodizing of magnesium and aluminum are contained within the specifications listed in Table 4.

Paint Systems. High-performance epoxy primers are used on navy aircraft due to their exceptional adhesion and chemical resistance in conjunction with their corrosion-resistance properties. The epoxide and hydroxyl groups of the epoxy resin react with polyfunctional amines or polyamides to form a highly corrosion-resistant thermoset polymer. These materials can be either solvent based or waterborne and utilize chromated corrosion-inhibiting pigments as their primary source of active corrosion inhibition. The use and disposal of carcinogenic chromate-containing materials is becoming severely

restricted, and efforts to develop primers with nonchromate inhibitor compounds are being performed. The performance requirements of these aerospace primers are contained within the military specifications listed in Table 5.

High-performance polyurethane paints are used to topcoat external aircraft surfaces following epoxy priming. These topcoats enhance corrosion protection and provide desired optical properties. The fundamental urethane reaction is that of an isocyanate with an alcohol. The combination of different isocyanates with the large number of available polyols makes possible the formation of a wide variety of polymers with varying physical properties. Aliphatic polyurethane coatings are mainly used for naval aviation due to improved weatherability performance as compared to aromatic polyurethanes. The use of these topcoats is indicated in Table 5.

New topcoat materials have been developed that virtually eliminate volatile organic compounds (VOCs) in aircraft paints based on the class W waterborne formulation. These new materials have shown equivalent characteristics to the standard class H high solids formulation in laboratory and field testing. Advantages of these products are no/low VOCs, enhanced cleanability, and improved application characteristics.

Triglycidylisocyanurate (TGIC) polyester powder coating has recently been approved for use as an alternate material to MIL-PRF-85285 polyurethane topcoat. Powder coating provides the additional benefits of improved corrosion protection and toughness with ease of application, decreased processing times, and decreased costs associated with environmental, safety, and

hazardous waste compliance. Powder coating materials require heat treatment for cure and, therefore, are not recommended for use with alloy systems in which metallurgical properties are negatively affected by powder coat bake temperatures of 190 to 200 °C (375 to 390 °F). Low-temperature cured powders of less than 120 °C (250 °F), however, are being investigated to expand usage across these alloy systems.

Sealants. The primary function of a sealant is to exclude moisture, contaminants, and fluids to protect the aircraft or substrate from an aggressive environment. The functional sealing requirements of aircraft are:

- Fuel tank sealing
- Environmental sealing
- Pressure sealing
- Sealing for severe corrosive environment
- Aerodynamic smoothing
- High-temperature and firewall sealing
- Sealing of windshields and canopies
- Sealing of honeycomb sandwich structure
- Electrical sealing and insulation

No single sealant will meet the major requirements of all applications. The selection of the most appropriate material should consider:

- Temperature and pressure
- Resistance to fluids
- Mechanical properties
- Adhesion
- Reparability

Mechanical exclusion of the environment is achieved by use of heavy films of low permeable

material having excellent adhesion. This process, however, can have disadvantages with equipment and components that are difficult to properly clean in preparation for sealing. This can result in poor adhesion and the entrapment of residual salts within crevices that provide a permanent source of corrosion. The use of chemical inhibitors incorporated into a sealant can provide added protection. Moisture that is naturally permeable through the sealant material can dissolve some of these inhibitors to provide additional passivation of the metal surface.

Sealing compounds used within naval aviation include polysulfides, polyurethanes, polythioethers, and silicones. Polysulfides, polyurethanes, and polythioethers are two-component systems consisting of a base (containing the prepolymer) and the accelerator (containing the curing agent). When thoroughly mixed, the catalyst cures the prepolymer to a rubbery solid. Rate of cure and sealant properties depend on temperature and humidity along with the types of catalyst and prepolymer selected. Silicone sealing compounds are one-component systems that cure by reacting with moisture in the air. Some silicone sealing compounds produce acetic acid as a condensation reaction by-product during cure, which can lead to severe corrosion problems. These sealants should be avoided.

A new commercially available off-the-shelf (COTS) polyurethane conductive gasket has been identified that provides electrical bonding between aircraft substrate and the mounting base of aircraft antennas and static discharger mounting bases. This technology is used to seal and protect components against moisture and subsequent corrosion while at the same time providing a mechanism for bonding and grounding and eliminating airborne communication precipitation static (P-static) discrepancies caused by corrosion.

The performance requirements of sealant compounds commonly used within naval aviation are contained in Table 6.

Examples of Aircraft Corrosion Damage

Example 1: Localized Corrosion. In Fig. 4, filiform corrosion damage is observed on aluminum exterior surfaces of a P-3 aircraft. In Fig. 5, the filiform damage is more evident in

Table 4 Specified coating performance requirements

Class	Description
MIL-DTL-81706 Chemical Conversion Coating Materials for Aluminum (Ref 4)	
Class 1A	Maximum protection against corrosion
Class 3	Protection where low electrical resistance is required
Form I	Concentrated liquid
Form II	Powder
Form III	Premixed liquid
Form IV	Premixed thixotropic liquid
Form V	Premeasured powder, thixotropic
Form VI	Premixed liquid (ready for use in self-contained applicator)
Method A	Spray
Method B	Brush
Method C	Immersion
Method D	Applicator pen
AMS-M-3171 Pretreatment and Corrosion Prevention of Magnesium Alloys (Ref 5)	
Type I	Chrome pickle treatment
Type III	Dichromate treatment
Type IV	Galvanic anodizing treatment
Type VI	Chrome acid brush-on treatment
Type VII	Fluoride anodizing process with corrosion preventative treatment
Type VIII	Chromate treatment
MIL-A-8625 Anodic Coatings for Aluminum and Aluminum Alloys (Ref 6)	
Type I	Chromic acid anodizing
Type IB	Chromic acid anodizing, low voltage (22 ± 2 V)
Type IC	Nonchromic acid anodize, type I and IB alternative
Type II	Sulfuric acid anodize
Type IIB	Thin sulfuric acid anodize, type I & IB alternative
Type III	Hard anodic coating
Class 1	Non dyed
Class 2	Dyed

Table 5 Performance requirements for coatings

Class or type	Description
MIL-PRF-23377 Epoxy Primer (High-Solids) (Ref 7)	
Type I	Standard pigment
Type II	Low infrared reflective pigments
Class C	Strontium chromate based corrosion inhibitors
Class N	Nonchromate based corrosion inhibitors
MIL-PRF-85582 Epoxy Primer (Waterborne) (Ref 8)	
Type I	Standard pigment
Type II	Low infrared reflective pigments

190 / Corrosion in Specific Environments

Table 6 Aircraft sealing compounds

Specification and type	Properties						Intended use
	Form(a)	Curing temperature	Service temperature, °C (°F)	Peel strength(b), kg/cm (lb/in.)	Corrosion inhibitors	Fluid resistance(c)	
MIL-PRF-81733 Sealing and Coating Compound, Corrosion Inhibitive (Polysulfide) Type I (thin): brush or dip application Type II (thick): sealant gun or spatula Type III (sprayable): spray gun Type IV (spreadable): extended assembly	2	Room	–54 to 120 (–65 to 250)	2.7 (15)	Yes	Yes	Sealing faying surfaces and for wet installation of fasteners on permanent structure repair
AMS-S-8802 (supersedes MIL-S-8802), Sealing Compound, Temperature Resistant, Integral Fuel Tanks and Fuel Cell Cavities, High Adhesion (Polysulfide) Class A (thin): brush application Class B (thick): sealant gun or spatula Class C (spreadable): extended assembly times	2	Room	–54 to 120 (–65 to 250)	3.6 (20)	No	Yes	Used for fillet and brush sealing integral fuel tanks and fuel cell cavities. Not to be exposed to fuel or overcoated until tack-free
AMS-3276 (supersedes MIL-S-83430), Sealing Compound, Integral Fuel Tanks and General Purpose (Polysulfide) Class A (thin): brush application Class B (thick): sealant gun or spatula Class C (thick): extended assembly times Class D (thick): hole and void filling Class E (thick): for automatic riveting equipment	2	Room	–54 to 180 (–65 to 360)	3.6 (20)	No	Yes	High-temperature applications. Used for fuel tank sealing, cabin pressure sealing, aerodynamic smoothing, faying surface sealing, wet installation of fasteners, overcoating fasteners, sealing joints and seams, and nonstructural adhesive bonding. For fuel tank applications, treat bond surfaces with AMS 3100 adhesion promoter to enhance sealant adhesion.
PR-1773 (supersedes PR-1403G), Sealing Compound, Non-Chromate Corrosion Inhibitive Polysulfide Rubber Class B (thick): sealant gun or spatula	2	Room	–54 to 120 (–65 to 250)	...	Yes	Yes	Air Force preferred sealant for general-purpose, low-adhesion sealing of access door and form in place (FIP) gasket
AMS 3267 (supersedes MIL-S-8784), Sealing Compound, Low Adhesion Strength, Accelerator Required (Synthetic Rubber) Class A (thin): brush application Class B (thick): sealant gun or spatula	2	Room	–54 to 120 (–65 to 250)	0.36 (2 max)	No	Yes	Fillet and faying surface sealing of removable structure such as access doors, floor panels and plates, removable panels, and fuel tank inspection plates. Not for high-temperature areas or permanent structure
AMS 3374 (supersedes MIL-S-38249), Sealing Compound, One-Part Silicone, Aircraft Firewall (Synthetic Rubber) Type 1 (one-part silicone): cures on exposure to air Type 2 (two-part silicone): addition cured Type 3 (two-part silicone): condensation cured Type 4 (two-part polysulfide): high temperature resistant	1	Room	–54 to 204 (–65 to 400)	1.8 (10)	No	Yes	Sealing firewall structures exposed to very high temperatures against the passage of air and vapors. Cures on exposure to air
MIL-S-85420, Sealing Compound, Quick Repair, Low Temperature Curing, for Aircraft Structures (Polysulfide) Class A (thin): brush application Class B (thick): sealant gun or spatula	2	Low	–54 to 93 (–65 to 200)	1.8 (10)	No	Yes	Cold temperature (5 °C, or 40 °F) and quick repair sealing of aircraft structures. Use only with recommended adhesion promoter. Not to be used when temperature exceeds 25 °C (80 °F) or poor adhesion will result
AMS 3277 (supersedes MIL-S-29574), Sealing Compound, for Aircraft Structures, Fuel and High Temperature Resistant, Fast Curing at Ambient and Low Temperatures (Polythioether) Class A (thin): brush application Class B (thick): sealant gun or spatula Class C (thick): extended assembly times	2	Low and room	–62 to 150 (–80 to 300)	3.6 (20)	Yes	Yes	Multipurpose aircraft structure and integral fuel tank sealants with rapid ambient and low-temperature curing capabilities. Use only with recommended adhesion promoter.
MIL-A-46146, Adhesive—Sealants, Silicone, Room Temperature Vulcanizing (RTV), Non-corrosive (Synthetic Rubber) Type I: paste Type II: liquid Type III: high strength	1	...	–57 to 204 (–70 to 400)	...	No	...	Convenient one-component sealant for use with sensitive metals and equipment. Not to be used where resistance to fuels, oils, or hydraulic fluids is required.
AMS 3255, Skyflex Sealing Tape, Polytetrafluoroethylene, Expanded (ePTFE) Class 1: Continuous Ribbed, includes: GUA-1071-1 for <1 in. wide faying surfaces GUA-1001-2 for >1 in. wide faying surfaces GUA-1003-1 compensation tape	PG	...	–54 to 120 (–65 to 250)	(2 max)	No	Yes	Sealing of faying surfaces, access panels, floorboards, and windscreens. Not for fuel-soaked or high-temperature applications. Nonhazardous alternative to two-component sealants

the macrograph. Corrective action included the removal of corrosion via glass bead blasting, cleaning, surface treatment, and reapplication of epoxy primer and polyurethane topcoat.

Example 2: Atmospheric Corrosion of Magnesium. A magnesium radar assembly (AZ-91C) was damaged from atmospheric exposure (Fig. 6). Corrosion was removed via glass bead blasting. MIL-C-81309 type III (Ref 8) corrosion-preventive compound was applied to unpainted surfaces to prevent recurrence.

Example 3: Pitting Corrosion. Aluminum alloy 7075-T6 seen in Fig. 7 experienced pitting corrosion damage. The damage to an EA-6B

aircraft lower longeron (fuselage structural member) resulted from water ingress and entrapment through fastener holes. Repair required removal and replacement with a newly manufactured item. Corrective action included design modification of drain holes and improvements to coating system with the addition of polyurethane topcoat.

Example 4: Internal Exfoliation. Figure 8 shows corrosion of an aluminum housing associated with the Barostatic Release Unit (BRU) of a F-14 ejection seat. Corrosion damage was the result of moisture entrapment at O-ring areas and required replacement of component. Corrective

action included the application of MIL-L-87177 corrosion-inhibiting lubricant.

Example 5: Exfoliation corrosion damage occurred on an aluminum P-3 integral fuel tank resulting from long-term exposure to moisture, salts, and fuel-system icing inhibitors (Fig. 9). Corrective action involved the mechanical removal of corrosion with powered abrasive sanders followed by surface treatment and application of AMS-C-27725 fuel tank coating.

Fig. 9 Exfoliation corrosion of a integral fuel tank on a P-3 aircraft resulting from long-term exposure to moisture, salts, and fuel-system icing inhibitors. Courtesy of J. Benfer, Naval Air Depot—Jacksonville

Example 6: Fretting corrosion damage occurred on the interior of an aluminum electrical wiring conduit located within the integral fuel tank of an EA-6B aircraft (Fig. 10). Through-wall corrosion damage resulted in significant fuel leaks, requiring the rerouting of electrical wires. Corrective action included the removal of wire bundle ties and application of additional protective coatings to newly installed conduits.

Example 7: Saltwater Intrusion. H-60 helicopter floor frame (aluminum alloy) corrosion around a floorboard mounting hole due to saltwater intrusion is shown in Fig. 11. Preventive measures included improved protective coatings and sealants and routine application of corrosion-preventive compounds.

Example 8: Galvanic Corrosion. AV-8 aircraft avionics mounting bracket (nickel-plated aluminum alloy) suffered the corrosion damage seen in Fig. 12. The aluminum alloy underneath the nickel plate corroded as a result of exposure to salt-laden air. Galvanic corrosion of the underlying aluminum alloy caused the nickel plate to blister and flake. Corrective measures included thicker nickel plating and routine application of avionics-grade corrosion-preventive compounds.

Example 9: Galvanic corrosion occurred on F/A-18 dorsal scallops and wing substructures. Composite doors are fastened to the aluminum

substructure with titanium or steel fasteners (Fig. 13). A more detailed view of mounting holes is seen in Fig. 14. Moisture migrated past the fastener head and set up a galvanic cell where corrosion began on the aluminum substructure around the fastener hole. To mitigate this corrosion, water-displacing corrosion-preventive compounds (CPCs) were applied to the shank of the fastener, and sealant was applied around its head during door installation. A design modification for new aircraft models eliminates this configuration.

Example 10: Exfoliation Corrosion. Figure 15 shows a T-45 access door corroded from moisture intrusion underneath electromagnetic interference (EMI) fingers (not shown). Direct metallic contact between access door and aircraft

substructure for control of EMI through the use of conductive EMI fingers prevents the usage of many protective coating systems. Corrective action is the frequent application of avionics-grade corrosion-preventive compounds and a recommended design change to incorporate the replacement of EMI fingers with a conductive sealant.

Example 11: General atmospheric corrosion of EA-6B slat gearbox limit switches prevented proper electrical and mechanical operation and resulted in increased maintenance (Fig. 16). Steel corrosion and rusting is prevented through the application of MIL-L-87177 corrosion-inhibiting lubricant (Fig. 17).

rective action was the use of improved corrosion-preventive compounds and redesign using corrosion-resistant stainless steel.

Example 15: Catastrophic failure of a F-14 nose landing gear cylinder seen in Fig. 21 was due to multiple fatigue crack initiation sites concentrated on the aft portion of the cylinder. The fatigue cracks initiated in a line of corrosion likely caused by contact of the thrust washer in the radius area. The contact removed the corrosion-protection system of paint and aluminum plating, permitting extensive corrosion around the cylinder circumference in the radius area.

Example 16: Hydrogen Embrittlement. F-14 arresting gear tail hook stinger catastrophically failed during an attempted arrested landing aboard a carrier. Failure occurred at the forward weld area and was the result of hydrogen embrittlement of the 300M high-strength steel. Figure 22 shows the component as received in the laboratory, and Fig. 23 is a macrograph of the fracture initiation area that was an area of high residual tensile strength.

Example 17: Damage Due to Improper Packaging. Newly manufactured EA-6B aluminum horizontal skin in Fig. 24 exhibited extensive corrosion as the result of water ingress from improper packaging and preservation during shipment from the manufacturer.

Conclusion

Aircraft corrosion is very expensive in terms of costs associated with inspection, maintenance and repair manpower, decreased aircraft availability, and loss of aircraft and human life. Aircraft operators and maintainers that operate in the harshest of conditions require the latest science and technology for corrosion control to include improved inspection, corrosion removal, and treatment processes. The application of good engineering practices with appropriate materials selection, design, and use of protective coating systems is necessary to ensure that naval aircraft weapon systems are both reliable and capable of performing their mission requirements.

Military Aircraft Corrosion Fatigue

K.K. Sankaran, R. Perez, and H. Smith, Boeing Company

CORROSION, FATIGUE, AND THEIR SYNERGISTIC INTERACTIONS are among the principal causes of damage to aircraft structures. Analysis of aircraft failure modes drawn from case histories from World War II showed that fatigue and corrosion accounted for 55 and 25% of the failures, respectively (Ref 1). A worldwide survey of 1885 aircraft accidents also showed that the proportion of fatigue failures directly attributed to the presence of corrosion was small (Ref 2). However, corrosion can still be a significant safety concern as it increases the stress in an airframe part by reducing the effective cross-sectional area of the structure carrying the load. Corrosion also causes stress concentrations, which can result in premature fatigue crack initiation. Therefore, the presence of corrosion reduces fatigue life and can result in a greater risk of failure of aircraft components. These problems are particularly relevant for "aging" aircraft, many of which, due to economic pressures, remain in service well beyond their initial design goals.

Corrosion is also a significant economic concern since the costs related to its detection, mitigation, repair, and maintenance are among the largest components of life-cycle costs for military systems. United States government studies conducted in 1996 and 2001 estimated the direct corrosion-related costs for military systems and infrastructure to be approximately \$10 billion and \$20 billion, respectively (Ref 3). These costs do not include the indirect costs resulting from the loss of opportunity to use the equipment while it is being repaired. The annual cost of corrosion for all aircraft systems in the United States in 1995 was estimated to be \$13 billion. Of this total, the share for the military was nearly \$3 billion to maintain its fleet of 15,000 aircraft, of which the Navy's share was about \$1 billion for its fleet of about 4600 aircraft (Ref 4, 5). An Air Force study determined the annual cost of direct corrosion maintenance to be about \$795 million in 1997. While the number of aircraft in the Air Force fleet decreased by 20% from 1990, the overall cost declined only 10% and aircraft-specific costs increased by 4% (Ref 6). Continuing assessments of the cost of corrosion to the Air Force show an increasing trend with the total costs increasing to about

\$1.1 billion in 2001 and \$1.5 billion in 2004 (Ref 7).

Many of the military aircraft presently in service were built prior to the availability of improved corrosion-control systems and alloys with superior corrosion resistance. Thus, corrosion will remain a concern until these aircraft are retired from service. While considerable emphasis has been placed on the detection and mitigation procedures for corrosion in these aircraft, the management of its effects on their structural integrity has received only limited attention principally due to the difficulty of quantitatively predicting the future effects of corrosion.

The effect of corrosion can be addressed by its superimposition on the methods presently used to predict fatigue life, which consists of a crack initiation period (including crack nucleation and microcrack growth) and a crack growth period (covering the growth of a visible crack to failure) (Ref 8). The development and validation of corrosion metrics that can be used as inputs into analytical fatigue life prediction models is critical to the superimposition of corrosion effect. A fundamental understanding of the corrosion mechanisms and corrosion/fatigue interactions under conditions that simulate aircraft service environment is necessary to satisfy this need. In the context of applying these concepts and methods for predicting and managing aircraft corrosion fatigue, the key topics and their interrelationships that are discussed in this article are outlined in Fig. 1.

Aircraft Corrosion Fatigue Assessment

The safe and economical operation of aircraft requires an accurate quantitative assessment of the effects of corrosion on the structural integrity of components. This assessment must be conducted in the context of the different approaches used to:

- Manage aircraft structural integrity
- Schedule aircraft inspection intervals
- Perform repair and maintenance of aircraft in service

The safe-life, fail-safe, and damage-tolerance approaches to the fatigue design and life assessment of aircraft structures and the methods used to address the additional effects of corrosion are described in *Fatigue and Fracture*, Vol 19, *ASM Handbook* (Ref 9). Unlike the effects of fatigue alone, the future occurrence and effects of corrosion cannot be predicted deterministically. Accordingly, the U.S. Navy, which manages the structural integrity of its aircraft using a safe-life approach to meet the safety and readiness demands of carrier operations (Ref 10), bases its maintenance practice on a "find it and fix it" corrosion repair philosophy. However, low levels of corrosion causing insignificant impact on fatigue and residual strength may not require immediate repair. While delaying repairs that can wait until a later maintenance cycle results in cost savings and higher fleet readiness, unfortunately there are no validated guidelines currently available for determining if a corrosion repair can be postponed without compromising safety.

The U.S. Air Force manages the structural integrity of its aircraft using fail-safe and damage-tolerance approaches (Ref 11). The combination of corrosion damage and fatigue is a problem in structures, and this problem will grow as the aircrafts continue to age in service. Corrosive environments and the resulting damage increase the stress in structural members, provide fatigue crack initiation sites, and accelerate crack propagation. The result is a component with shorter fatigue life and reduced residual strength. A report issued by the National Materials Advisory Board of the National Research Council has provided a detailed assessment of the effects of corrosion on the safety limits and the inspection intervals for both fail-safe and safe-crack-growth-designed aircraft. It has recommended research and development programs to address these issues (Ref 11).

The subject of corrosion and its effects on fatigue and aircraft structural integrity have been discussed in comprehensive reviews (Ref 12, 13). The proceedings of a NATO Applied Vehicle Technology Panel workshop titled *Fatigue in the Presence of Corrosion*, contains many papers in the areas of in-service experience with corrosion fatigue, fatigue prediction methodologies in corrosive environments, and effects

of corrosion/fatigue interactions on structural integrity (Ref 14).

To ensure structural integrity, the undamaged aircraft structure must withstand specified flight maneuvers and must be designed to sustain limited damage between scheduled inspection intervals (Ref 15). Loads anticipated during aircraft service and the resulting fatigue damage are well understood and used for predicting the life of components undergoing mechanical loading. Aircraft components are subjected to fatigue loading only during flight, but can experience corrosion throughout their calendar life. Since it is difficult to determine precisely the onset and progression of corrosion damage, its effects on the fatigue life of aircraft components cannot be accurately predicted. Accordingly, there have only been a very few attempts to incorporate the effects of corrosion in analytical models to predict the life of aircraft components in service (Ref 16). See the article "Predictive Modeling of Structure Service Life" in Volume 13A.

Prior Corrosion Damage as Equivalent Initial Flaw. Corrosion damage in aircraft structures results in an initial flaw size that can reduce the predicted life of a critical component and render noncritical components as critical (Ref 13). Therefore, approaches to incorporating the effects of corrosion have so far focused on developing and validating models for life prediction using data from fatigue tests conducted

on relevant materials and corrosion environments to simulate in-service experience of aircraft structures.

Commonly used tests to obtain data for fatigue design and analysis include the stress-life, strain-life, and fatigue crack growth tests (Ref 17, 18). Data on the simultaneous influence of corrosion exposure and fatigue loading can be obtained by testing pristine specimens (specimens without prior corrosion exposure) in selected corrosive environments. While they can provide information on the mechanisms of corrosion fatigue crack nucleation and growth, it is difficult to accurately simulate the in-service interactions between corrosion and fatigue in these tests.

More useful data for modeling the effects of corrosion can be obtained from tests conducted in ambient environments using specimens already containing varying levels of corrosion damage caused by controlled exposure to corrosive environments prior to fatigue loading. The corrosion damage at the start of the test (prior corrosion) can be treated as an "equivalent flaw" whose effect on the fatigue life can be determined in these tests. Quantitative measures or metrics for corrosion can then be used as the "size" of the equivalent flaws in order to predict life in a manner similar to that used for predicting fatigue life in the absence of corrosion. The goal is to validate this approach to predicting the life of aircraft components containing measurable

corrosion damage, which can be treated as "prior corrosion" and which can be detected during inspection. Achieving this goal requires the definition and validation of quantitative metrics for the various corrosion types experienced by aircraft, development of probabilistic models for the evolution of future corrosion and fatigue damage, followed by their use directly in fatigue life prediction models.

Causes and Types of Aircraft Corrosion

Military aircraft operate under harsh and widely varying conditions that differ significantly from commercial aircraft. Naval aircraft, such as the F/A-18 deployed in carriers, are subjected to the ocean environment as well as to the exhaust fumes in below-deck areas. Flexing of aircraft structure and maintenance activities can damage corrosion-protection systems, which can become scratched and can crack around fasteners. These processes allow the intrusion of water, salt, and other contaminants into the structural joints and initiate corrosion. The article "Corrosion in Commercial Aviation" in this Volume discusses the various types of corrosion observed in aircraft and provides numerous examples of corroded components.

The types of corrosive attack observed in aircraft structures include uniform, galvanic, pitting, filiform, fretting, intergranular, and exfoliation corrosion, and stress-corrosion cracking. These types of corrosion result in combinations of localized attack (pitting), bulk material loss (galvanic or exfoliation corrosion), and general surface roughening (uniform, filiform, or fretting corrosion). Stress-corrosion cracking can occur in susceptible alloys exposed to tensile stresses and corrosive environments. Crevice corrosion occurs when discrete areas on an alloy are physically isolated or occluded such as at joints in aircraft structures. Crevice corrosion can eventually cause surface grain separation in the surrounding part resulting in severe intergranular or exfoliation corrosion and a volumetric increase from the corrosion products (pillowing), which can increase the stress and crack growth rates (Ref 19).

Commonly used aircraft structural materials such as the high-strength aluminum alloys possess heterogeneous microstructures, which render them susceptible to corrosion. The problem is compounded when they are used in conjunction with dissimilar materials in the assembly of aircraft parts. For example, corrosion is common in aluminum alloy hinges used in military aircraft. Hinges contain copper alloy (beryllium copper) bushings at the lug holes and galvanic corrosion can occur at the bushing/aluminum-alloy interface (Fig. 2). Figure 3 shows an example of exfoliation corrosion around a fastener hole in a longeron (a major airframe structural member running from the front to the rear of an aircraft and oriented in the longitudinal axis of the fuselage). Longerons are typically fabricated

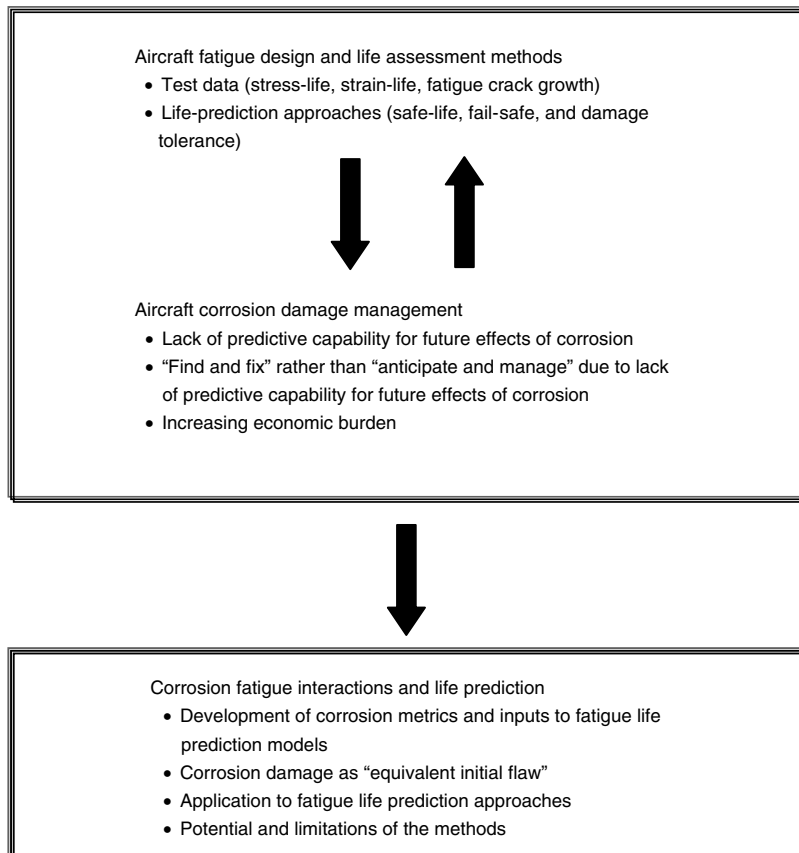

Fig. 1 Military aircraft corrosion fatigue status and assessment approach

from high-strength aluminum alloy extrusions. An example of crevice corrosion and pilling is shown in Fig. 4, where a 2024-T4 aluminum alloy fuselage skin is spot welded to a 2024-T4 doubler. Pilling due to the accumulation of the corrosion products in the joint can be seen.

Impact of Corrosion on Fatigue

To varying degrees, all the observed forms of corrosion damage can reduce the load-carrying capacity of the aircraft structure, initiate fatigue cracks, and increase fatigue crack growth rates. As discussed earlier, in the absence of a corrosive environment at present, fatigue cracks can nucleate in structures with prior corrosion damage. Fatigue cracks can also nucleate from simultaneously developing corrosion damage due to the concurrent influence of fatigue loading and corrosive environment. The results of a large number of investigations on the effects of prior corrosion or the presence of a corrosive environment on fatigue crack initiation and growth in high-strength aluminum alloys (commonly used aircraft structural materials) can be summarized in the context of their schematic stress-fatigue life (cycles to failure) behavior (Ref 12):

- Prior corrosion has a large effect on fatigue life and decreases the lives significantly at all stress levels. This is because, at any given stress level, the life of specimens with preexisting damage will always be lower than those without such damage.
- Prior corrosion is more detrimental than continuous corrosion at high stresses and relatively short lives. This is because at the high stress levels that result in low fatigue lives, sufficient corrosion damage may not develop in the available time in the environment prior to fatigue failure.
- The concurrent effect of a corrosive environment and fatigue loading is synergistic at lower stress levels and relatively longer fatigue lives because corrosion damage continues to accumulate with time. Thus in the presence of a corrosive environment, the fatigue life will continue to decrease more rapidly with increasing stress compared with the lives in the absence of a corrosive environment.

Fig. 2 Corrosion of an aluminum alloy hinge (7050-T74) around a copper alloy bushing (UNS C17200, beryllium copper)

Since corrosion causes stress concentrations, prior corrosion will reduce the fatigue lives of materials. This is illustrated by the measured fatigue lives of 7075-T6 aluminum alloy specimens with and without prior corrosion damage (Fig. 5) (Ref 20). The corroded 7075-T6 specimens contained varying amounts of damage caused by exposing them to various durations in the prohesion salt-spray test (ASTM G 85, Annex 5). Prohesion used to describe this test was derived from “protection is adhesion.” The measured lives are also compared with the values

contained in the *Metallic Materials Properties Development and Standardization Handbook* (MMPDS, formerly MIL-Handbook-5) for the fatigue lives of bare 7075-T6 alloy without any prior corrosion damage (Ref 21). The MMPDS values are plotted for lives of specimens at values of stress-concentration factor, K_t , of 1 (smooth specimen with no surface stress concentration) and $K_t = 2$ (specimen containing a geometrical discontinuity that raises the local stress at the discontinuity to two times the nominal stress applied to the specimen). The R value of 0.1 is

Fig. 3 Exfoliation corrosion around a fastener hole in a 7049-T73 aluminum alloy longeron. Radial arrows indicate measurements taken to assess damage.

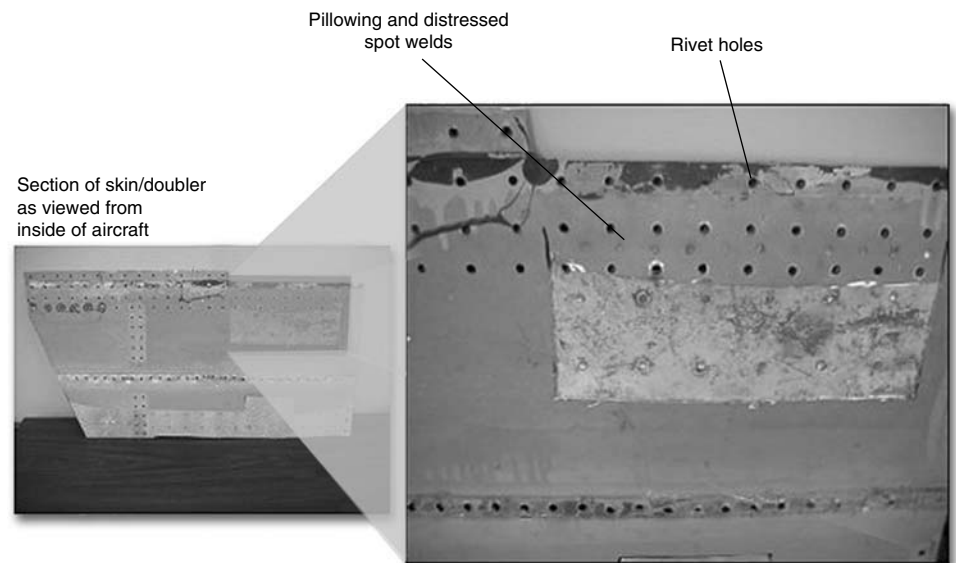

Fig. 4 Corrosion pilling on aircraft skin at joint. Aluminum alloy 2024-T4 skin is joined to doubler by spot welding and with fasteners (2017-T3). Rivet holes for the lap joint are seen in the lower (inside) portion of the joint.

the ratio of the minimum stress to the maximum stress applied in each load cycle during the fatigue test.

A continuous decrease in fatigue life with increasing prior corrosion damage is observed. It is interesting to note that the measured fatigue lives for 7075-T6 containing various levels of prior corrosion damage are bounded by the design handbook values for noncorroded 7075-T6 at K_t values of 1 and 2. The observation that the magnitude of the reduction of the fatigue lives by prior corrosion is similar to that due to a geometric flaw or discontinuity suggests that equivalent stress-concentration factors attributable to corrosion damage could be used as a measure or metric to quantitatively describe the effects of corrosion.

In polycrystalline materials, preexisting damage will initiate a fatigue crack immediately upon the application of load (Ref 22). Therefore, in specimens with prior corrosion, a fatigue crack can be expected to initiate and grow from the first load cycle, whereas specimens without prior corrosion require time for corrosion damage to accumulate and to initiate and grow fatigue cracks. The effect of prior corrosion is thus more detrimental at higher fatigue stress levels. At lower stress levels corresponding to longer fatigue lives or larger number of cycles to failure, the effects of corrosion and fatigue can be expected to be synergistic.

Difference in Military and Commercial Aircraft. The nature of corrosion/fatigue interactions has broad implications on the life assessment of military aircraft, which typically fly fewer hours than commercial aircraft and accumulate fatigue damage at a slower rate but corrosion damage at a higher rate (Ref 12). Thus, the principal need is to quantify the structural performance of critical areas of aircraft with the assumed presence of prior corrosion in the representative environment that is present during service. Because corrosive environments such as salt water are typically absent during flight, many of the corrosion fatigue investigations have concentrated on the testing and modeling of the fatigue behavior of materials and components with prior corrosion but in-flight service in a

benign environment. However, the need also exists for understanding and accounting for the effects of the corrosive environments during flight service, as such cases have been reported (Ref 23). Development and use of metrics to represent the different types of observed corrosion is necessary to satisfy these needs.

Corrosion Metrics

Corrosion detected during aircraft inspection is frequently described qualitatively as “light,” “moderate,” or “severe,” which precludes a quantitative assessment of its effects on the structural integrity. The problem is being overcome by applying fracture mechanics principles and modeling damage from corrosion in a manner similar to that caused by fatigue cracking (Ref 24). Geometric parameters such as pit dimensions, surface roughness, loss of metal thickness, and volume increase due to pitting can be used to quantitatively characterize types of corrosion. These metrics, in turn, have the potential to be integrated into corrosion fatigue models to assess structural integrity.

Pitting Corrosion Metrics. Pitting is a common form of corrosion experienced by structural materials such as the high-strength aluminum alloys used in the aerospace industry. This type of corrosion has received considerable attention because it initiates fatigue cracks. It is almost always present with other types of corrosion, and crack initiation can frequently be traced to a pitlike defect. Further, it is relatively easy to characterize quantitatively to obtain metrics for use in life prediction models.

In high-strength aluminum alloys, pit formation is associated with the various types of constituent particles in the microstructure (Ref 25). Depending on the relative electrochemical difference between the particles and the aluminum matrix, pits are nucleated either by the dissolution of the aluminum matrix or the constituent particles, which are typically equiaxed and 25 to 50 μm in size. Each pit is generally associated with a particle on the alloy surface and reaches a depth approximately equal to the particle size. However, particles are also often present in clusters, which nucleate pits that have been found to extend to a depth of 300 μm in 2024-T3 (Ref 26). The morphology of pitting lends itself to quantitative description by parameters such as density (number of pits per unit area), depth, and length. Both laboratory studies on aluminum alloy 2024-T3 (Ref 27, 28) and 7075-T6 (Ref 20), as well as analysis of failed aircraft parts (Ref 23) have demonstrated that pits are sites for fatigue crack initiation.

Documented cases of fatigue cracks initiating from corrosion pits in 7xxx series alloys have also shown that crack growth was promoted by the environment until failure of the components occurred. Analysis of the causes of failure of a Royal Australian Air Force aircraft showed that the trailing edge flap failed at its outboard hinge and twisted upward about the inboard hinge

(Ref 23). During a fleet inspection, cracking was detected in the 7050-T74 (formerly 7050-T73652) hinge lug in two other Australian aircraft. Corrosion pitting was found in the majority of the lug hole bore surfaces, and fatigue cracks initiated from the pits in both aircraft. In one aircraft, the corrosion pits reached an average depth of 200 μm , and the largest pit was 290 μm deep. In the other aircraft, the average pit depth was 150 μm . The investigation concluded that the flap failure was caused by fatigue cracks initiating at corrosion pits.

Research concentrating on corrosion metrics for steels has received less attention than that for aluminum alloys in the aerospace industry. Cadmium plating typically protects steel alloys, and the breakdown of the plating results in the corrosion of steel. However, this mechanism of pitting is not the same as that observed in aluminum alloys, which possesses a passive layer and whose breakdown results in surface pitting. Nevertheless, the “equivalent flaw size” approach has been used to account for corrosion pitting in D6AC steel (UNS K24728 with nominal composition of Fe-0.46C-1.00Cr-1.00Mo-0.55Ni, a medium-carbon, ultrahigh-strength, quench-and-temper steel commonly used for highly stressed aircraft parts (Ref 29). This study was undertaken to incorporate pitting corrosion damage into fatigue life modeling and to avoid unnecessary maintenance of F-111 aircraft. Localized pitting damage was induced in the D6AC steel specimens by electrochemical means.

Surface Roughness Parameters. Production processes such as chemical milling and etching are used in the fabrication of military aircraft parts. These processes result in surface roughness similar to that caused by pitting corrosion. Thus, the standard surface roughness parameters measured from characterization methods such as profilometry (which are used in production processes) should also be applicable to corrosion damage characterization (Ref 30). Commonly used surface parameters include the roughness average, roughness height rating, root-mean-square roughness, and total indicator runout. Some of these parameters have been related to the observed dimensions of pits nucleating fatigue cracks in etched specimens of aluminum alloys (Ref 30).

Surface Corrosion and Thickness Loss. Thickness reduction caused by surface corrosion has been identified as a parameter for modeling corrosion damage. Increased stress caused by the reduced cross section has been incorporated in the stress-intensity factors used in fatigue crack growth predictions (Ref 31). While the decrease in cross section caused by the corrosion was reflected in the stress intensity, it did not completely account for the higher crack growth rates measured at lower stress intensity. Further work is needed to determine if other factors, such as embrittlement, affected the crack behavior.

Exfoliation Corrosion and Pitting. Exfoliation is a severe form of intergranular corrosion in materials with directional grain

Fig. 5 Fatigue properties of unexposed and corroded, 0.080 in. thick 7075-T6 sheet. Data of various exposure times of prohesion corrosion spray test are compared to MMPDS Handbook data. Stress-concentration factor $K_t = 1$ is smooth specimen, $K_t = 2$ has a discontinuity that doubles stress. R is the ratio of minimum stress to maximum stress applied each cycle.

structure, typical of rolled or extruded high-strength aluminum alloys. It originates at exposed end grains, for example at fastener holes, and is characterized by flaking that causes leaflike bulging as the corrosion products accumulate (Ref 32). This type of corrosion leads to a loss of metal capable of carrying load. When exfoliation occurs in joints, the corrosion products cause a volumetric increase, or pillowing, as shown schematically in Fig. 6 and in Fig. 7. Extensive documentation of this phenomenon has shown that the skin volume increases by more than 300% (Ref 33). This in turn, causes high local stresses and rivet head fracture (environment-assisted cracking) where the rivet head meets the shank. The increase of corrosion product volume by exfoliation is typically 6.5 times greater than that predicted by thickness lost. Finite-element analysis has shown that pillowing causes significant stresses. Testing confirms that cracks initiate in the highly stressed areas predicted by the analysis (Ref 34).

Compared to pitting corrosion, the modeling of exfoliation corrosion has received much less attention, although exfoliation and pillowing are significant and escalating maintenance problems. This may be partly due to the difficulty of geometrically modeling the exfoliation corrosion morphologies as equivalent initial flaws for fatigue crack initiation, as well as the complex interactions of loading with the corrosion damage. Attempts have been made to identify a "corrosion process" zone with exfoliation corrosion and to relate the observed fatigue lives

to the dimensions of this zone (Ref 35). An investigation of 7075-T6 specimens with exfoliation damage representative of damage occurring in service showed that fatigue lives decreased with increase of the depth of exfoliation (Ref 36).

The metrics used to describe corrosion damage are either highly qualitative (light, moderate, severe) or very detailed (individual pit dimensions) so as to be difficult to measure in the field. The challenge is to relate the metrics developed in the laboratory to damage parameters from inspection of in-service aircraft and to validate the relationships by correlation of life estimated from models using damage metrics with that observed in service. To enable such a correlation, it is necessary to understand the nucleation and growth of corrosion, nucleation and growth of fatigue cracks from corrosion sites, and the process of corrosion fatigue in detail.

Investigations and Modeling of Corrosion/Fatigue Interactions

It is difficult to accurately simulate in-service aircraft conditions in the laboratory. How the effects of corrosion/fatigue interactions during the relatively short military aircraft flight periods are related to those of corrosion alone during the relatively long ground times is not entirely known. Other factors such as type of accelerated corrosion test and environments, specimen geometries, loading conditions, corrosion-protection systems, and their degradation all need to be representative of service conditions.

Accelerated corrosion test methods, designed to approximate in a short time the corrosion-deterioration effects under normal long-term service conditions, have been developed for evaluating various types of corrosion such as pitting, crevice, and exfoliation. ASTM standards have been developed for performing such tests. In the aerospace industry, accelerated laboratory corrosion tests, principally spray tests, are used extensively to evaluate the corrosion susceptibility of alloys and coatings for screening of materials and quality control.

Several environments are currently being evaluated in spray corrosion tests with the intention of simulating service environments. The most commonly used of these is the neutral salt-spray environment consisting of a 5% NaCl solution (ASTM B 117). The SO₂/salt-spray test (ASTM G 85, Annex 4) is used to simulate the performance of alloys in environments such as those present in aircraft carriers. These environments are quite aggressive to many aluminum alloys. The recently developed prohesion test (ASTM G 85 Annex 5), a modified salt-spray test that combines a wet-dry cycle with a dilute environment of lower Cl⁻ ion concentration, is already recognized as providing a more realistic simulation of corrosion attack than the neutral salt-fog or the SO₂/salt-spray tests (Ref 37).

The validity of the accelerated tests for generating corrosion growth rate data for life prediction of aircraft structures remains to be verified. Nevertheless, these tests are useful in providing an understanding of the nature of corrosion/fatigue interactions in alloys and environments of interest, and considerable progress has been made in this regard. The premise here is that these tests can be useful if the corrosion damage obtained in these accelerated tests is similar to that found in service. Pitting and exfoliation corrosion, followed by crevice corrosion and pillowing, have received the most attention.

Pitting Corrosion and Effects on Fatigue. In studying the effects of corrosion on fatigue behavior, the influence of both preexisting corrosion as well as corrosive environments on fatigue crack initiation have been considered. For the latter case, corrosion/fatigue interactions have been modeled by the testing of pristine specimens in a corrosive environment during which fatigue and corrosion damage accumulate simultaneously. In these models, corrosion pits are considered as surface cracks whose growth rates are determined by the pitting kinetics (Ref 27, 38, 39). A fatigue crack nucleates from the corrosion pit either when the pit grows to a critical size at which the stress-intensity factor (K) reaches the threshold for fatigue cracking (Ref 38) or when the fatigue crack growth rate (da/dN) exceeds the pit growth rate (Ref 39). A recent study of alloy 2024-T3 showed that both these criteria are needed for adequately describing the transition from pitting to fatigue crack growth (Ref 27).

During the service life of an aircraft, the structure typically experiences corrosion between flights and fatigue loading during flight, thus pointing to the need for delineating the effects of prior corrosion on fatigue behavior. In this context, Harmsworth conducted the first quantitative study of the influence of preexisting corrosion on reducing the fatigue life of aluminum alloys (Ref 40). In this study, the amount of corrosion in alloy 2024-T4 was measured as a function of exposure time. Decreasing fatigue lives were observed with increasing corrosion exposure (pit depths).

Pitting-corrosion/fatigue interactions can be modeled by using pit dimensions as inputs into fatigue life prediction models. Quantitative measures such as pit dimensions and surface roughness have been used as metrics to describe corrosion, and their potential feasibility in combination with crack growth analysis tools in estimating fatigue life of components subjected to corrosion has been demonstrated (Ref 30). In this study, the measured fatigue properties of etched (pitted) 2124-T8 and 7050-T74 aluminum alloys compared reasonably well with those calculated analytically using equivalent initial flaw size assumptions. A series of criteria were also described for ranking various corrosion metrics to enable selection of the applicable parameter for structural analysis. Prior corrosion pitting was also found to reduce the fatigue

Fig. 6 Corroded lap joint showing pillowing mechanism

Fig. 7 Overall surface appearance of panels representing a fuselage skin joint. 7075-T6 alloy skin with 2017 fasteners was exposed 110 days in an ASTM copper-assisted salt solution spray test.

strength of aluminum alloys 2024-T3 and 2524-T3 at 10^5 cycles by approximately 40% (Ref 41). Crack growth analysis was used in this study to predict the fatigue lives (the number of cycles needed to grow the fatigue crack to its critical size) and to investigate the effects of the alloy compositions and pit morphology on the fatigue lives.

In a similar systematic investigation, the effects of preexisting localized surface pitting corrosion damage on the fatigue lives of alloy 7075-T6 were measured and compared with the predicted lives using measures of corrosion (metrics) obtained from a characterization of the corrosion damage (Ref 20). Pit depth histograms resulting from exposing bare 7075-T6 sheets for up to 1536 h exposure in the prohesion test (ASTM G 85 Annex 5) were determined, and the observations of damage evolution were found to be consistent with the nucleation/growth/decay nature of the pitting process. Fatigue crack growth models were used to predict the life (the number of cycles needed to grow the fatigue crack to its critical size) of 7075-T6 specimens containing various levels of pitting damage. The measured lives generally agreed with the predictions using the average pit size as the initial crack size. This result was explained as due to the pit size distributions offering a significant population of pits near the average size. A continuous decrease in fatigue life with increasing pit dimensions (increasing corrosion exposure) was observed. For the purposes of simulating corrosion/fatigue interactions, the prohesion spray test enables a more controlled and progressive evolution of corrosion damage, amenable to systematic characterization, compared with the commonly used but more aggressive neutral or acidified salt sprays.

While the salt spray and its modifications using standardized corrosion environments provide accelerated corrosion rates and are in common use to screen the relative corrosion susceptibility of materials, they may not be representative of the corrosive environments experienced by aircraft structure. To address this issue, the corrosion products found in crevices in aircraft joints have been analyzed and the chemistry of these products from one such joint was used to reconstitute a representative solution. Interestingly, the crevice environment for a 2024 joint in this case was found to be alkaline, and the alloy showed no tendency to pit when subjected to this environment in the laboratory. This finding suggests that the crevice environment in an aircraft at a given time may not be representative of the overall environmental history of the joint.

In all of these investigations, fractographic examination of broken corrosion fatigue specimens clearly show that the dominant fatigue cracks nucleate from corrosion pits, whose depths are typically in the 50 to 250 μm range.

Exfoliation, Crevice Corrosion, and Effects on Fatigue. The current “find it and fix it” corrosion repair philosophy requires that even the smallest amount of exfoliation damage should be

removed, even if its effect on structural integrity is not known. Fatigue testing of specimens prepared from aluminum alloy 7178 wing skins removed from a commercial aircraft showed that specimens with 29% of exfoliation penetration through the skin lasted two lifetimes (twice the number of cycles that the structure was designed to operate without failure) without cracking, whereas specimens in which the exfoliation corrosion was repaired by grind-out had significantly lower fatigue lives (Ref 42). This study suggests that repair by grinding produces effects that may be more detrimental than exfoliation corrosion. Unfortunately, the level of acceptable corrosion itself is not known. It should be noted that these observations were from fatigue tests with compression-dominated loading spectra and may not hold true for tension-dominated loading spectra. In a different study, an evaluation of the effects of exfoliation of the 7075-T6 upper wing skin of the C141 aircraft showed that the fatigue lives decreased with increase of exfoliation depth (Ref 36).

In investigating the effects of corrosion of lap joints, varying amounts of pillowing must be obtained without the pillowing stresses causing failure of the fasteners. An example of pillowing resulting from the exposure of specimens representing a fuselage lap-splice joint is shown in Fig. 7. The specimens were fabricated from clad aluminum alloy 7075-T6 sheet (1.6 mm, or 0.063 in., nominal thickness) and 2017 aluminum alloy fasteners. Aluminum alloy products, particularly sheet and tube, are clad with a layer of a different aluminum alloy that is 80 to 100 mV more anodic than the core to provide cathodic protection to the core alloy. Alloys 7008, 7011, and 7002 are commonly used for cladding 7075. In clad alloys, corrosion progresses to the core/cladding interface and then laterally, thus eliminating perforation of thin products (Ref 43).

The clad 7075 skin lap-splice specimens with 2017 fastener specimens were exposed in a corrosion chamber using a modified ASTM copper-assisted salt solution (CASS) test. The result of metallographic sectioning of a specimen excised from the corroded panel is shown in Fig. 8. The amount of thinning varied from 0.051 to 0.127 mm (0.002 to 0.005 in.). This relatively low level of material thinning corresponds to an average of about 5% thickness loss. The use of the ASTM CASS test with a lap joint representative of fuselage skins has been shown to induce corrosion in the faying surfaces. While the cladding layer has been consumed, the 7075 core had not suffered corrosion damage in 110 days of continuous exposure (Fig. 8). Despite this low level of corrosion, the volume of corrosion products was sufficient to cause pillowing. Additional work is necessary in determining appropriate electrolytes that will provide varying levels of measurable corrosion in reasonable exposure times, from which metrics for exfoliation corrosion can be developed and the effects on fatigue behavior can be determined.

Effects of Corrosion Mitigation. Corrosion prevention compounds (CPCs) are being used more during aircraft maintenance for mitigation of future corrosion. While intended as temporary protection for regions of damaged coatings and exposed surfaces, presently CPCs are also being used in the manufacture of original equipment (Ref 44). Environmental regulations are also requiring the substitution of new nonchromated systems for the proven chromated systems. The effects of CPCs on fatigue behavior of aircraft joints are mixed and depend on the type of joints and loading conditions. Further research is required to reliably predict their effects. In a recent study, application of CPCs to 2024-T3 coupons with prior corrosion extended the remaining fatigue life by as much as a factor of up to 2.5 over specimens with similar corrosion but no CPCs (Ref 45). Similarly, prior corrosion had less effect on the fatigue performance of joints with CPCs in which the fasteners also remained tight.

Figure 9 presents the results of constant amplitude fatigue testing of chromate conversion coated 7075-T6 specimens further treated with primers and tested in four different conditions, treated with: a chromated primer, two different nonchromated primers, and no primer (tested as conversion coated) (Ref 46). For each of these

Fig. 8 Corroded lap joint of 7075-T6 skin with 2017 fasteners. (a) Specimen from panel exposed in the ASTM CASS spray test show pillowing and attack of cladding. (b) Micrograph cross section show loss of cladding, but no loss to the 7075-T6 core. Original magnification: 200 \times

four conditions, six specimens—three without any prior corrosion exposure and three with 1536 h exposure to the prohesion corrosion environment (ASTM G 85, Annex 5)—were fatigue tested at a maximum stress level of 55 ksi and R ratio of 0.1. The fatigue cycles to failure for specimens with and without the corrosion exposure are shown by the shaded and unshaded bars, respectively. Corrosion exposure resulted in a decrease in the fatigue lives of all specimens except those with one of the nonchromated primers. Development of new environmentally compliant systems is presently aimed primarily at achieving corrosion-protection performance approaching that of chromated systems. Their corrosion fatigue behavior under service conditions needs to be characterized to assess effects on structural integrity.

Methodologies for Predicting the Effects of Corrosion on Fatigue

The two most common fatigue life assessment methods used in the military aerospace industry are fatigue crack initiation and crack growth analysis.

Crack initiation analysis uses stress-life or strain-life curves to predict the number of flight hours for crack initiation, which is typically defined to occur when a fatigue crack of 0.25 mm (0.01 in.) length is present. The analysis of crack initiation is the basis for the safe-life design methodology (Ref 10), which defines the flight hours for crack initiation (the crack initiation life or the design life) for a component to be equal to a safety factor times the desired operating life (the number of desired flight hours without crack initiation) for that component. A safety factor of 4 is typically used

if the airframe will be subjected to a full-scale fatigue test. Full-scale test articles are typically required to undergo two simulated operating lifetimes without crack indications. In other words, in this case, the airframe is designed to four lifetimes before crack initiation (presence of a 0.25 mm, or 0.01 in., length crack) and tested to two operating lifetimes. If a full-scale test will not be completed for a particular component, a larger safety factor can be required in the design criteria.

Major users of the safe-life design methodology include the U.S. Navy and the U.S. Army for designing dynamic aircraft components. The reasons for adopting this approach vary by application. In U.S. Navy aircraft carriers, for example, the ability to inspect aircraft for fatigue cracks and perform structural repairs is very limited when compared to land-based facilities. As a result, the U.S. Navy has adopted the safe-life approach to minimizing the occurrence of cracks larger than 0.01 in. in length.

An important parameter in the safe-life analysis is the stress-concentration factor, or K_t , which depends on the geometry of a discontinuity such as a hole or notch. Harmsworth documented the first incorporation of corrosion fatigue test data into the prediction of fatigue crack initiation by using test data to determine stress concentrations as a function of corrosion magnitude (Ref 40).

Recently, an attempt has been made to develop a corrosion fatigue life prediction procedure that accounts for variations in the magnitude of corrosion. The measured fatigue life data for specimens with varying levels of prior corrosion were used to perform an extensive probabilistic analysis to determine the corrosion-induced stress-concentration factor for aluminum alloy 7075-T6 (Ref 47). To supplement

the measured test data, crack growth analysis was used to predict the number of cycles to initiate 0.01 in. long semielliptical cracks in the corroded specimens for which the measured pit sizes were used as the initial flaw dimensions. This analysis can provide a distribution of fatigue lives (equal to the number of cycles needed to initiate a 0.01 in. crack) for a given stress level corresponding to the distribution of the measured pit sizes for a given degree of corrosion damage. The analysis can then be repeated for various stress levels. This analysis was conducted for 7075-T6 specimens with an open-hole ($K_t = 3$) geometry without corrosion as well as with superimposed initial flaw sizes corresponding to the characteristic, 5th and 95th percentile values for the Weibull distribution of the pit dimensions for a given corrosion damage. The results are plotted (Fig. 10), which shows the predicted stress-life curves for 7075-T6 specimens with an open-hole geometry without corrosion ($K_t = 3$) curve and with three levels of initial flaw sizes (5%, char, 95% corresponding to the characteristic, 5th, and 95th percentiles values for the Weibull distribution of the pit dimensions for a given corrosion damage, in this case corresponding to the 96 h of corrosion exposure shown in Fig. 5).

The reduction in fatigue life is typically related to an increase in the stress-concentration factor. The concentration (or notch) factor associated with a given level of corrosion damage is then the ratio of the stresses at a particular life for the noncorroded specimen and the corroded specimen. Sets of stress values at a given fatigue life (cycle) can be read from plots such as those shown in Fig. 10. The ratios of the stress values corresponding to the noncorroded specimens to those for the three curves are used to obtain the required notch factors corresponding to the characteristic 5th and 95th percentile values of the pit dimensions.

A metric required to characterize the level of corrosion on a particular specimen was chosen to be directly related to the size of the pits. The intent was to make the method valid for any corrosive environment and one that could then be used in the field to quantify the corrosion severity

Fig. 9 Effect of various corrosion protection schemes on the fatigue behavior of 7075-T6 alloy. Six samples were fatigue tested from each protection scheme. Fatigue test maximum stress 380 MPa (55 ksi), $R = 0.1$. The white bars had no prior corrosion exposure. The three shaded bars in each set were exposed to 1536 h prohesion corrosion environment.

Fig. 10 Predicted fatigue lives for 7075-T6 alloy, open-hole geometry specimens with superimposed corrosion damage. Open-hole without corrosion damage, $K_t = 3.0$ curve. as well as to correlate with the corrosion notch factor. The pit norm metric is defined as:

$$\text{Pit norm} = \sqrt{l^2 + w^2 + d^2}$$

where l is pit length, w is pit width, and d is pit depth. The pit norm was computed for each of the individual pits measured on each corroded test specimen. A Weibull distribution was fit to each set of the pit norms, and the characteristic value was found. The corrosion notch factors computed from Fig. 10 were plotted against the characteristic pit norm for that data set. The results are shown in Fig. 11 from which the distribution of the notch factor for a given amount of corrosion can be determined. The pit norm is the metric used to characterize the corrosion, and the notch factor is the quantity used to assess the effect of that amount of corrosion on the life of the component.

To use the data in Fig. 11, the surface pitting corrosion is first characterized in terms of pit sizes by computing the pit size norm for a sufficient number of pits that adequately represents the extent of corrosion in a part. The best-fit Weibull distribution to the pit norm data defines the characteristic value. For this value, the effective notch factor and the range representing the 5th to 95th percentile of the expected distribution of the notch factor can then be determined. As can be observed in Fig. 11, the corrosion notch factor for aluminum alloy 7075-T6 varies from 1.0 (for limited corrosion) to 2.25 (for more severe corrosion). This ability to analyze corrosion with respect to some quantitative severity scale such as a “notch” factor has the potential to enable its incorporation in the assessment of structural integrity using safe-life methods.

A study of 2xxx series aluminum alloys also concluded that the effect of corrosion on a part can be modeled by a stress-concentration factor and that even light corrosion can reduce the crack initiation life by effectively increasing the local stress by 18% or more (Ref 48).

Crack growth analysis methods use fracture mechanics to predict the number of flight hours

for the initial flaw to grow to failure. These techniques form the analytical basis of the damage tolerance analysis (DTA) design philosophy (Ref 9), developed by the U.S. Air Force in response to the crash of an F-111 aircraft in 1969. This approach centers on the assumption that a preexisting flaw is located at the critical area in a part. Because a flaw that can propagate under cyclic loading is present, there is no crack initiation period. The assumed initial flaw size is defined by the minimum inspectable flaw that can be detected. A typical initial flaw size used in industry is 1.25 mm (0.05 in.) in length. The predicted crack growth life (the flight hours needed to grow the crack to its critical length) is divided by a safety factor of two to define the inspection interval for the part.

Because the initial flaw used in DTA is typically much larger than the dimensions associated with corrosion damage, the effect of corrosion can be easily covered by DTA. The effect of environment can also be included during DTA by using the crack growth rate behavior for the environment and by representing the loss of thickness by a corresponding increase in stress.

Boeing has assessed the corrosion damage effects with respect to specific DTA. The corrosion model used for the analyses assumed corrosion damage limits for specific part details. Those limits were either the minimum thicknesses associated with repairs or an overall pre-defined maximum thickness loss. Both limits are defined by an operating stress equal to the design strength for the part. The outcome of this analysis was a revised inspection schedule accounting for corrosion damage. Details with unacceptable inspection intervals were identified for pre-engineered repairs. For the KC-135 aircraft, while the fuselage lap joints are not critical, some fuselage panels with spot welded joints, which are located in corrosion-prone areas, are being replaced due to corrosion damage. Replacement of those joints is again based on inspection results (visual clues confirmed by nondestructive inspection). One complex problem in this DTA is the uncertainty about future corrosion. A joint with light corrosion could be accepted without

significant repairs needed. However, continuing corrosion could take the joint past an acceptable level of damage prior to the next programmed depot maintenance cycle. This corrosion state is a moving target that needs to be accounted for in the acceptance criteria for fuselage joints.

Although DTA can incorporate the effect of corrosion on a primary crack, its effects at multiple locations also need to be addressed. Widespread corrosion can lead to multisite damage. In the case of pitting corrosion, fatigue cracking from individual pits needs to be modeled in addition to the analysis of the dominant flaw in the DTA. This issue has been addressed in several ways such as by using pit growth models to predict when a pit is large enough to produce a crack that exceeds the fatigue crack growth threshold (Ref 39) or by modeling the deepest pit as the equivalent initial crack (Ref 24).

The fatigue damage and failure induced by pitting corrosion are composed of seven stages: pit nucleation, pit growth, transition from pit growth to short crack, short crack growth, transition from short crack to long crack, long crack growth, and fracture. In studying the effects of preexisting corrosion on fatigue behavior, pit nucleation and growth are not relevant in DTA, but the nature of transition from the pit to a short crack and short crack growth need to be clearly delineated. The transition from pit growth to short cracks covers the initiation of fatigue cracks from the pits. Short crack growth has been characterized by faster crack growth rates than observed for larger cracks (>0.25 mm, or >0.01 in.) at the same stress-intensity value, K (Ref 49). As short cracks continue to grow, they transition to long cracks that propagate in accordance with the standard da/dN versus ΔK curves for the particular alloy. Available life prediction methods are adequate once the cracks grow beyond the “short” crack stage.

In a study in which the transition from pit to a crack is assumed to occur when the crack growth rate exceeds the pit growth rate, the fatigue crack growth curve for long crack data was modified to account for the crack growth rate of the small cracks. This modification affected the lower end of the curve where the threshold stress-intensity factor changed from 2.4 to 1.2 MPa(m)^{1/2} (Ref 38).

The U.S. Air Force is developing a holistic structural assessment method under an initiative to develop analytical tools to assess the effects of corrosion on aircraft structural integrity (Ref 50). Models for the effects of surface corrosion (pitting and general) and corrosion pilling in joints as well as the growth of fatigue cracks from the corrosion are available in this method. In experiments conducted during the development of this method, the fatigue lives of 7075-T6 specimens were reduced significantly after natural corrosion exposure for 3 months with little further reduction upon exposure up to 12 months. This initial reduction of fatigue lives was attributed to the formation of an “influential” pit following, while further exposure had only a minor effect on fatigue life. Scanning electron

Fig. 11 Corrosion notch factor (corrosion severity) as a function of characteristic pit norm corrosion metric. Notch factors were computed for data of Fig. 10.

microscopy examination of the fracture surface showed that the pits at crack origin were typically 75 to 100 μm deep. Based on a holistic life assessment, it was suggested that the "influential" pit should be 100 to 150 μm deep with an aspect ratio of 3 to 1. Many of the other investigations discussed earlier also showed a large reduction of fatigue lives, however, at corrosion damage levels corresponding to much smaller measured pit depths.

Recent Development and Future Needs

In response to the significant cost and readiness impact resulting from corrosion, a new U.S. federal law was enacted in Dec 2002, which created a Department of Defense-wide corrosion prevention and mitigation program for both equipment and infrastructure. Several initiatives are underway, ranging from the formation of a "Corrosion Prevention and Control Integrated Product Team," and establishing a "Corrosion Information Exchange Network," to development and testing of materials, processes, and treatments to combat corrosion. Planning for corrosion prevention and control is now a requirement for most Department of Defense programs (Ref 7). This new corrosion policy can be expected to have an overall positive impact in mitigating the effects of corrosion/fatigue interactions.

Significant progress has been made in modeling the environments and corrosion growth experienced by various aircraft (Ref 11). A major difficulty in the development and validation of methods to assess the effects of corrosion is the lack of correlation between actual in-service corrosion damage and corrosion fatigue failures with those observed in the laboratory. Testing of structural components removed from aircraft under conditions that simulate the aircraft environment is invaluable in this regard. One difficulty the authors have experienced is that a component removed from the aircraft and made available for testing has already undergone a few maintenance cycles in which the corrosion has been typically removed and the component is cleaned or it is beyond repair and hence not useful for testing.

The nature of accelerated testing needs to be studied further. Whereas it is useful to study the corrosion effects on laboratory specimens, some meaningful link must be made back to the nature of the corrosion experienced in the field. It would be very helpful if time-scale references could be determined between life in the field and exposure in the laboratory. The ability to correlate damage observed in the field with standardized metrics and with the results of nondestructive inspection is also important. Techniques such as laser profilometry have been used recently to map and quantitatively characterize the surfaces of corroded specimens (Ref 51). The corrosion metrics determined from this technique were successfully used to predict the lives of 7075-T6

specimens with prior corrosion. Laser and white light profilometry and other similar techniques need to be developed and demonstrated for obtaining corrosion metrics from the field and for use in life prediction models.

Corrosion of Electronic Equipment in Military Environments

Joseph T. Menke, U.S. Army

CORROSION OF ELECTRONIC EQUIPMENT became a concern when electrical components left the 50% relative humidity and 20 °C (70 °F) controlled environment of the rooms that computers first occupied. Electronic equipment went from labs, banks, and offices to aircraft, tanks, ships, and missiles. These pieces of equipment experience the cold of winter, the heat of the desert, the salt spray of the ocean, the moisture-condensing conditions of landing aircraft, or the pressure spray washing conditions that maintenance operations may entail. The corrosivity of solder flux residues and etching solutions, and the cleanliness testing of printed circuit boards (PCBs) prior to conformal coating, became issues in the manufacturing process to lessen corrosion problems. Potting, hermetic sealing, conformal coating, and other operations were the design and manufacturing attempts for survival of the electronic components in adverse environments.

An Historical Review of Corrosion Problems

Some of the earliest information on the deterioration of electronic equipment is found in Greathouse and Wessel's treatise *Deterioration of Materials: Causes and Preventive Techniques*, published in 1954 (Ref 1). The chapter on electronic equipment identified the environmental concerns as temperature, moisture, biological growth, rain, salt spray, sand and dust, and shock and vibration. It further identified the deterioration of plastic insulating materials as a significant problem of the time. In 1958, military standard 441 was prepared by the Navy's Bureau of Ships, which essentially addressed the reliability of military electronic equipment (Ref 3).

Prior to the standard, military electronic equipment was "reliable" when procured, because all the testing was performed on new systems. The use of mean-time-to-failure data gathering for purposes of establishing replacement electronic parts was unique. Equipment was allowed to age in the environment, and

maintenance consisted of changing parts or assemblies to keep the equipment operational. The basic corrosion concerns of the 1960s were the deterioration of the physical properties of the materials involved in electronic equipment. A report in 1967 compared the fungus resistance of vinyl polymer insulating cable coverings (Ref 4). A 1963 Bell Telephone Labs report described a procedure for reducing the embrittlement of gold-plated solder joint (Ref 5). A gold-tin intermetallic compound was formed during soldering, and the thickness of the gold plating had to be reduced to minimize the amount of gold penetrating/dissolving in the solder that produced the brittle joint.

In 1965, Rock Island Arsenal evaluated the corrosive effects of sleeving materials, tapes, varnishes, sealing compounds, and molded plastics on materials such as zinc, cadmium, steel, magnesium, and copper (Ref 6). In 1965, the cover of *Chemical and Engineering News* magazine (Ref 7) described corrosion as "a plague from space to razor blades." The article was an excellent review of corrosion; however, the reference to corrosion as a "plague" became commonplace in the electronics industry. "Red plague" was used to describe the red corrosion product observed on silver-coated copper wire (Ref 8). The silver plating was the cathode. Because small pores are generally present in the thin plating, galvanic corrosion of the copper occurred and was accelerated by the large cathode/small anode relationship. The resulting red corrosion product of cuprous oxide (Cu_2O) was formed in the presence of water and oxygen. "Purple plague" has been identified as an intermetallic compound that forms when a gold wire is bonded to an aluminum pad (Ref 9). Time and temperature can affect the solid solubility of gold and aluminum. When the compound AuAl_2 is formed, the purple color of the intermetallic is evident. An example of purple plague is shown in Fig. 1. "Blue plague" was used to describe the oxidation of tin coatings as a result of solder reflowing operations. "Green plague" described the green corrosion product of copper/copper chloride that forms on tin-plated copper wire and on bare copper surfaces when solder flux resi-

dues are not properly removed (Ref 10). "White plague" was used to describe general corrosion of solder material on PCBs. "Worm plague" was used to describe the selective leaching of lead from lead-tin solder joints that corroded in contact with antistatic materials impregnated in pink poly bags used for cushioning and packaging of PCBs. There are probably other "plagues" in the electronics industry, but it is important to note that the front cover of Ref 7 had a more lasting effect than the actual article on corrosion. In 1966, S.M. Arnold of Bell Laboratories reported the presence of tin whiskers (hairlike metallic growths) on tin-plated items of electrical equipment (Ref 2). It has not been determined to this day (2006) if surface oxides, intermetallics, or some other mechanism caused the residual stress necessary for whisker growth. Finally, in the October 1968 edition of *Metal Finishing*, various chemical etchants were evaluated for controlling the undercutting problems of nickel/gold coatings on copper for PCB manufacture (Ref 11). Control of the undercutting was essential to prevent trapping of the etchant residues on the PCB.

An interesting change began to occur in the 1970s. Actual components from electronic hardware began to be evaluated for corrosion resistance. In 1971, the Electronics Command (ECOM) investigated general corrosion caused by the effects of plastics decomposition products on beryllium-copper contacts (Ref 12). In 1974, ECOM investigated the effects of corrosion on waveguides (Ref 13). Galvanic corrosion, crevice corrosion, and stress-corrosion cracking were highlighted as specific corrosion problems associated with these components. In 1975, the Tank and Automotive Command highlighted the corrosion on components such as relays, starters, and motors (Ref 14). In 1979, a report was written on electrical contacts in submarine-based electronic equipment (Ref 15). This report was a first attempt at considering the effects of specific environments of a system (submarine) on component parts (electrical contacts.) It addressed the materials involved in the component parts and the specific types of corrosion that occurred. The 1970s also brought about different concepts

of finishing contacts. The military was gold plating most of the high-reliability items, while industry was using tin plating (Ref 16, 17). This conflict often resulted in tin-plated contacts on PCBs being inserted into gold-plated beryllium-copper connectors. The resulting galvanic corrosion destroyed the tin-plated contacts and the electrical function of the board. Also, the classification of white tin corrosion products on solder joints as cosmetic contributed to the confusion of the situation.

In the 1980s, a more technical approach to electronics corrosion had evolved with the identification of the types of corrosion being experienced on electronics hardware. Electronics corrosion symposia were conducted at the University of Minnesota and the National Association of Corrosion Engineers annual corrosion conferences. The Army originally published MIL-STD-1250 as a corrosion prevention and deterioration control document for electronic components and assemblies in 1967. It was updated in 1992 and was changed to MIL-HDBK-1250 in 1995 (Ref 18). In 2001, it was designated "inactive for new design" as a result of acquisition reform. In 1983, the Navy published a document (Ref 19) entitled "Design Guidelines for Prevention and Control of Avionic Corrosion." It described the effects of the environment and the types of corrosion failure with Naval equipment. In 1988, the author was provided an "Air Force Lessons Learned" summary that detailed the major cause of electronic corrosion as a water intrusion problem (Ref 20). The Air Force papers cited water contamination in parts per million causing

problems with hermetically sealed microcircuits. The Army was experiencing moisture in the ounces range in taillights and other black boxes. The Navy was also experiencing saltwater contamination in gallon quantities in the electronics onboard aircraft carriers. This situation typifies the electronic corrosion problems with military equipment.

Examples of Corrosion Problems

Importance of Design for Corrosion Control. Looking at individual pieces of equipment today (2006) can illustrate the electronic corrosion problems. The typical "electronic black box" is used to contain electrical equipment that provides various functions (Ref 21). The worst assumption that one can make is that the box is hermetically sealed. Webster's dictionary defines *hermetic* as fused, which implies soldered, brazed, or welded. It does not mean an O-ring seal, potted connector, or some similar organic material seal. Rubber seals, for example, often leak because of the physical properties of rubber. Unconfined rubber occupies a known volume, but under a load, the rubber tends to extrude outward. Knowing that rubber extrudes rather than compresses requires that the O-ring groove be large enough to allow for this extrusion. Otherwise, the rubber will extrude out of the groove during tightening, and a seal is not formed. Diurnal cycling can result in moisture condensation that produces a humidity cabinet environment inside the electronic box, vehicle taillight, or similar electronic devices. Two other

adverse properties of rubber in service are ozone cracking and compression set. When these phenomena are experienced on supposedly sealed electronic devices, water can get in and cause serious corrosion problems.

Thus, the design should allow the box to breathe if it is not hermetically sealed. The main problem is that if the box is almost hermetically sealed, water can get in and, most likely, cannot get out. If the inside gets wet, a drain hole is one approach that can be used to allow the water to run out. The system can then breathe, and, if it gets wet, it can also dry out so that minimal corrosion may be encountered. A drain hole in the vehicle taillights would have resulted in a longer useful life for these components. Another approach may be used in lieu of or in conjunction with a drain hole. Volatile corrosion inhibitors (VCIs) will protect multimetal surfaces that are usually present in electronic devices. The VCIs can be used in semisealed units of various sizes for up to one year. Testing has shown that VCIs in a sealed plastic bag with PCBs can protect against 4000 h of humidity cabinet exposure, with no adverse effects on the PCB components. It should be noted that not every VCI is a multimetal formulation and that the older VCIs formulated for protecting bare steel are generally unsuited for electronic component protection.

The next aspect of an electronic box is the position of the PCBs. The PCBs should be positioned in the vertical plane, not the horizontal plane. In the horizontal plane, dust, dirt, salt, moisture, and even mold can accumulate on the surface of the PCB. When a drop of water bridges two traces on a board that are at different voltages, the high-voltage lead becomes the anode and starts to corrode. Figure 2 shows the result of an electrolyte bridging two circuits on an electronic board. The low-voltage lead becomes the cathode, and ions that went into solution can begin to plate out at the cathode. When the plating reaches the anode, a short circuit is created, and the board ceases to function properly. Often, military boards are given a conformal coating so that water drops are prevented from contacting the circuits. However, all organic coatings are permeable to water vapor. Pure water under a conformal coating does not cause an immediate problem, because pure water is nonconducting. If the board is contaminated with solder flux residues, circuit etching salts, or other conductive materials under the conformal coating, a failure can be expected, because a conductive path under the conformal coating is created. In addition, water can be trapped inside electrical connectors. Figure 3 shows the result of an electrolyte trapped inside an electrical connector. The Army has 690, 1380, 2760, and 5520 kPa (100, 200, 400, and 800 psi) steam cleaners in the field for use by soldiers to perform certain types of maintenance. These devices can blow water past most types of rubber or O-ring 35 kPa (5 psi) seals, trapping the water inside. Another way in which horizontally positioned boards become contaminated with electrolyte is through spillage and runoff of soda beverages.

Fig. 1 Example of purple plague. The failure characteristics often associated with purple plague are increased electrical resistance and lower mechanical (bond) strength.

Coffee spillage was encountered on PCBs mounted in the flight control unit of a C-5 aircraft. Figure 4 shows the result of the coffee spill in the contact area. Naval electronic maintenance personnel have suggested that black boxes have a pointed top (shaped like a doghouse) to prevent liquid containers from being set on the devices.

The third aspect of the black box design is proper location of the connectors for insertion of the PCB. Locate the board connectors on the side or the top, not the bottom. In design, there is a natural tendency to locate the connectors in the bottom of the electrical box, especially if the access door to the unit is on the top. The original control units in the Bay Area Rapid Transit cars were an example of this design. Rundown of moisture and debris accumulates in the contact area in the bottom of the box. This results in electrolyte bridging and shorting between the individual connector tabs and the PCB contacts, causing corrosion and eventual failure of the system. With the connectors on the side or the top and the PCBs in a vertical position, corrosion due to moisture accumulation is minimized.

Proper positioning or location of the internal connectors is the next consideration for the feed-through connections. The design should locate the feed-through connectors on the side of the black box. Water accumulation in sump areas around a feed-through located in the bottom can completely corrode the highest-voltage lead, rendering the unit totally useless, as shown in Fig. 5. Moisture-proof (environmental) connectors can provide a false sense of security, based on the wicking nature of multistrand wire or coaxial leads. Any nick, slit, or hole that penetrates the sheathing and/or insulation allows moisture to enter the cable, wick along the strands, and enter the black box through the connector. Fasteners holding the feed-through in place are also potential paths for electrolyte to leak into the electrical box. Drip loops need to be included in the external lead wires coming to the feed-through to keep water out of the system.

Material Considerations. The basic material used for circuitry on PCBs and in general wiring is copper. Connectors may be made of phosphor bronze or beryllium-copper alloys. The coating applied to the connectors and circuits is generally gold plating, to provide solderability, conductivity, and corrosion resistance for

maximum reliability. In other instances, tin plating, lead-tin plating (solder plating), or silver plating may be used on various components. It is essential to use similar metals on the connectors, PCB contacts, and circuits to prevent galvanic corrosion. Gold in contact with tin or solder plating will result in severe galvanic corrosion of the tin or solder plating. Figure 6 shows tin-plated contacts that were inserted into a gold-plated beryllium-copper connector in the horizontal position.

Another materials problem in electronic design that is unfamiliar to many electrical engineers is solid-solution phenomena or the formation of intermetallic compounds when certain materials are in contact with each other. Soldering of gold surfaces to tin-coated surfaces results in an intermetallic gold-tin compound that forms a brittle solder joint. The effects of solid-solution phenomena are best illustrated when gold and copper are in intimate contact with each other. This results when the copper circuitry or copper contacts are gold plated. Because the gold is typically 1 μm (40 $\mu\text{in.}$) or less in thickness, the gold is slowly diluted by the copper migrating (via solid solution) through the gold layer to the surface. As the copper content in the gold surface increases, a general blackening (copper oxidation) of the surface occurs. The typical cleaning technique prior to soldering for maintaining the board contacts is to use a pencil eraser (soft abrasive) to get rid of the black (copper) corrosion product. To prevent the solid solution and thus the subsequent corrosion from occurring in the first place, an antidiffusion coating of nickel or cobalt is required between the copper and gold. The same antidiffusion coating can be used between silver plating on copper wire or tin plating on copper wire to prevent corrosion of these coated wires. Figure 4 shows contact surfaces that were gold plated, with the rest of the circuits on the board left with the tin coating. While this can save money, the presence of the electrolyte and the horizontally positioned board allowed electrolyte to permeate the conformal coating, and galvanic corrosion attacked the tin at the gold-tin interface. In recent years, the amount of silver plating used on electrical equipment has been decreasing because of past problems with silver migration and the formation of silver whiskers. Silver can

Fig. 3 Effects of water being trapped inside a connector. The high-voltage pin (anode) is completely corroded off (right side), while the ground pins (cathodes) exhibit no corrosion. The pins in between are at lower voltages and show a lesser degree of corrosion.

Fig. 4 White corrosion products on tin-coated circuits and galvanic corrosion between the gold-tin contact/circuit interface resulting from a coffee spill

Fig. 5 Effects of water accumulation in the sump area of a black box. The arrow points to the high-voltage lead wire that has completely corroded, rendering the unit nonfunctional. Note that the connector is wrongly positioned horizontally inside the box.

Fig. 2 Schematic showing an electrolyte bridging two circuits on an electronic board. (a) Transverse view of the board. (b) Top-down view of the circuits on the board. Source: Ref 22

plate out across circuits, similar to the shorting shown in Fig. 2, when the circuits are at different potentials. However, silver can also plate out across nonconductive surfaces by a dissolution/plating mechanism that also creates an electrical short between two conductors. In addition, most

of the corrosion products of silver are conductive, while almost all other conductive metals have corrosion products that resist the flow of current. Figure 7 shows silver sulfide whiskers that formed on the surface of a copper pin that was plated with silver and gold (Ref 23). The

silver migrates through the gold coating and reacts with sulfur-containing elements in the air, forming the silver sulfide whisker. This photo was taken of a connector procured for use in missile components. Substitution of a nickel undercoating for the silver coating eliminates this problem. In the past, alloying the tin coating with 1.5% Pb helped to eliminate the tendency for whiskers to occur. Due to the elimination of lead in electronic devices, reflowing the tin by heating (a form of stress relief) also seems to minimize the tendency for whisker formation. Because of the wide variety of metals that are used in the design of electronics, the properties and interactions of these materials must be better understood to effectively improve the reliability of electrical equipment.

Effects of Contaminants. Small quantities of not-so-obvious contaminants can also have disastrous effects on black boxes. These contaminants, probably the most elusive, are produced by materials that emit corrosive vapors. Do not use any material in electronic equipment that may emit corrosive vapors. Materials that emit corrosive vapors include chlorinated organic compounds such as polyvinyl chloride (PVC) insulation on electrical wiring. Polyvinyl chloride is the least expensive and most widely used commercial wiring insulation material available. This insulation decomposes with time at temperatures from ambient to 120 °C (250 °F) to form hydrogen chloride gas. Figure 8 shows how heating can accelerate the decomposition of the insulation material. The hydrogen chloride gas reacts with moisture to form hydrochloric acid, a very corrosive material even at low concentrations. A list of military specification insulation materials for wiring that contain PVC can be found in Ref 24.

Bubble pack cushioning materials seem to be used everywhere today (2006), and that includes electronic devices. These materials may contain

Fig. 6 Tin-plated contacts (a + A) that have been completely corroded as a result of being inserted into a gold-plated beryllium-copper connector. Electrolyte was retained as a result of the board being in the horizontal position.

Fig. 7 Silver sulfide whiskers growing on a copper pin that was coated with silver plating followed by gold plating

Fig. 8 Two solder connections that were made without a heat sink. The solder area was hot enough to initiate the thermal decomposition of the polyvinyl chloride insulation. The continuing decomposition of the insulating material resulted in the release of hydrogen chloride gas to the inside of the electronic unit.

another chlorinated organic compound, polyvinylidene chloride. Polyvinylidene chloride has very low oxygen permeability and maintains the "cushy" properties of the bubble pack material. Dual-in-line packages (DIPs) with nickel- and gold-plated Kovar (Fe-29Ni-17Co) leads, wrapped in bubble pack and heat sealed in polyethylene craft paper, were found blistered and corroded after two years in storage. The corrosive environment caused rust on the Kovar substrate to bleed out onto the surfaces of the gold leads. Exposure of the DIPs with bubble pack wrapped around them and heat sealed in 0.13 mm (5 mils) polyethylene to a 100% humidity test for one month reproduced the corrosion problem. The testing included using pink polyethylene used for antistatic packaging purposes, and the results showed severe corrosion where the antistatic material touched the nickel- and gold-plated Kovar surface. Newer bubble pack materials use nylon in place of the polyvinylidene to eliminate the corrosive decomposition products of the older bubble pack materials.

Alkyd paints containing drying oils can liberate organic acids (mainly formic acid) in various quantities that will attack zinc, iron, cadmium, and other metals. It has been reported that these vapors may continue to be evolved in quantities sufficient to cause corrosion for 15 months. Catalytically cured paints (epoxies, urethanes, etc.) should be used, because corrosive vapors are not emitted during the curing of these materials. Certain room-temperature vulcanizing (RTV) silicone adhesive sealants react with moisture in the air and emit acetic acid vapors. These acetic-acid-emitting materials do not meet specification MIL-A-46106 (Ref 25) and should not be used for sealing or potting electronic units. Acetic acid vapors confined in a sealed electronic unit will corrode zinc, steel, cadmium, magnesium, copper, and aluminum.

To seal electronic units, the noncorrosive RTVs that evolve methanol on curing should be used. The noncorrosive RTVs meet military specification MIL-A-46146 (Ref 26). A listing of corrosive and noncorrosive RTVs is also available in Ref 24. Additional materials that may

emit corrosive vapors are identified in Ref 27. Effects of air pollutants and other contaminants on the reliability of electronic items have also been the subject of papers authored by Frankenthal (Ref 28), Douthit (Ref 29), and others (Ref 30). The design of telephone exchange buildings (actually an oversized black box) incorporates various materials to avoid corrosive vapors. Cinder block is not used in the construction because it contains iron sulfide and can subsequently result in the formation of sulfurous acid vapors. White adhesives for floor tile and latex paints are not used because they contain morpholine and ammonia, respectively. The air is filtered to remove chlorides and makes only one pass through the building, because nitrous oxides are formed during switching operations. All of these considerations are very important in preventing the corrosion of the electrical switching equipment.

Summary. Figure 9 shows an electronic black box that has boards in the horizontal position, a feed-through connector on the bottom, PVC insulation on the internal wiring, no drain hole, and tin contacts in a gold-plated connector. The box was sealed with an O-ring seal that is ozone cracked at the corners, and painted externally with an alkyd paint. The unit value was in excess of \$10,000 and required constant depot maintenance to keep it working.

In most cases with electronic equipment, the corrosion experienced is based on the individual properties of the material/finish exposed to some environment. The military environment includes any area of the world where troops may be deployed—cold climates, deserts (sand/dust), jungles (tropics), sea coastal, and marine environments. When the environmental concerns are added to the long-term life performance expectancies of military hardware (some systems today, 2006, are approaching 50 years), the corrosion resistance associated with the environmental exposure must be a real consideration during the initial design of the equipment. One of the few descriptions of various environments is found in ANSI/EIA-364-B (Ref 31). The environmental classes are:

Class number	Definition
1.0	Year-round filtered air conditioning with humidity control
1.1	Year-round air conditioning (nonfiltered) with humidity control
1.2	Air conditioning (non-year-round) with no humidity control
1.3	No air conditioning or humidity control with normal heating and ventilation
2.0	With normal ventilation but uncontrolled heating and humidity
2.1	Year-round exposure to heat, cold humidity, moisture, industrial pollutants, and fluids
3.0	Outdoor environment with moisture, salt spray, and weathering
4.0	Aircraft environment (uncontrolled)

The testing procedures associated with accepting parts intended for these environments are also described in this standard.

In the area of corrosion maintenance for electronic equipment, the Navy has prepared a

document, NAVAIR 01-1A-509, for cleaning and corrosion control (Ref 32). The Navy found that 40 to 50% of the boards could be returned to service just by pulling out the board and reinserting it—in effect, cleaning the contacts of corrosion products. They also found that over 90% of the failed weapon removable assemblies could be returned to service when trained technicians followed the manual. This Navy document has been adopted for use by the Air Force and the Army in the maintenance of their electronic equipment. The Air Force has determined that using MIL-L-87177A (Ref 33) lubricant on the contacts can prevent deterioration. Testing of this lubricant by Battelle showed that this lubricant provides corrosion protection for the contacts, while some other contact lubricants were actually corrosive to the contact materials.

Microbiologically Influenced Corrosion in Military Environments

Jason S. Lee, Richard I. Ray, and Brenda J. Little, Naval Research Laboratory, Stennis Space Center

MICROBIOLOGICALLY INFLUENCED CORROSION (MIC) designates corrosion due to the presence and activities of microorganisms. Microorganisms can accelerate rates of partial reactions in corrosion processes and/or shift the mechanism for corrosion (Ref 1). Most laboratory and field MIC studies have focused on bacterial involvement; however, other single-celled organisms, including fungi, can influence corrosion. This article focuses on MIC of military assets and is divided into atmospheric, hydrocarbon and water immersed, and buried environments. Individual mechanisms for MIC are discussed for specific examples. More general discussions of MIC are found in the articles "Microbiologically Influenced Corrosion" and "Microbiologically Influenced Corrosion Testing" in *ASM Handbook*, Volume 13A, 2003.

General Information about Microorganisms

Liquid water is needed for all forms of life, and availability of water influences the distribution and growth of microorganisms. Water availability can be expressed as water activity (a_w) with values ranging from 0 to 1. Microbial growth has been documented over a range of water activities from 0.60 to 0.998. Microorganisms can grow in the temperature range in which water exists as a liquid, approximately 0 to 100 °C (32 to 212 °F). Microorganisms can grow over a range of 10 pH units or more (Ref 2). Many microorganisms can withstand hundredfold or greater variations in pressure. The highest pressure found in the ocean is slightly inhibitory to growth of many microorganisms. Heavy metal concentrations as low as 10^{-8} M can inhibit the growth of some microorganisms, while others may continue to grow at concentrations of a millionfold or greater. Microbial species show thousandfold differences in susceptibility to irradiation (Ref 3).

Microorganisms also require nutrients and electron acceptors. All organisms require carbon, nitrogen, phosphorus, and sulfur, in addition

to trace elements. Microorganisms can use many organic and inorganic materials as sources of nutrients and energy (Ref 2). Organisms that require oxygen as the terminal electron acceptor in respiration are referred to as aerobes. Anaerobes grow in the absence of oxygen and can use a variety of terminal electron acceptors, including sulfate, nitrate, Fe^{+3} , Mn^{+4} , and others. Organisms that can use oxygen in addition to alternate electron acceptors are known as facultative anaerobes. Microbial nutrition and respiration are coupled and adapted to environmental conditions. Additionally, microorganisms living in consortia can produce growth conditions, nutrients, and electron acceptors not available in the bulk environment.

Atmospheric Corrosion

Because fungi are the most desiccant-resistant microorganisms and can remain active down to $a_w = 0.60$ (Ref 4), they are the microorganisms most frequently involved in atmospheric MIC. Most fungi are aerobes and are found only in aerobic habitats. Fungi are nonphotosynthetic organisms, having a vegetative structure known as a hyphae, the outgrowth of a single microscopic reproductive cell or spore. A mass of threadlike hyphae make up a mycelium. Mycelia are capable of almost indefinite growth in the presence of adequate moisture and nutrients so that fungi often reach macroscopic dimensions. Spores, the nonvegetative dormant stage, can survive long periods of unfavorable growth conditions (drought and starvation). When conditions for growth are favorable, spores germinate.

Biodeterioration due to fungi has been documented for the following nonmetallic military assets: cellulose (paper, composition board, and wood); photographic film; polyvinyl chloride films; sonar diaphragm coatings; map coatings; paints; textiles (cotton and wool); vinyl jackets; leather shoes; feathers and down; natural and synthetic rubber; optical instruments; mechanical, electronic, and electric equipment

(radar, radio, flight instruments, wire strain gages, and helicopter rotors); hammocks; tape; thermal insulation; and building materials. Fungi cause corrosion in atmospheric environments by: acid production, indirect dissolution of coatings, or direct degradation of coatings. Direct degradation is related to derivation of nutrients. Fungi assimilate organic material and produce organic acids including oxalic, lactic, formic, acetic, and citric (Ref 4).

Researchers isolated the following fungal genera from polyurethane-coated 2024 aluminum helicopter interiors (Ref 5): *Pestalotia*, *Trichoderma*, *Epicoccum*, *Phoma*, *Stemphylium*, *Hormoconis* (also known as *Cladosporium*), *Penicillium*, and *Aureobasidium* (Fig. 1). Several genera, including *Aureobasidium*, penetrated the polyurethane topcoat but not the chromate primer. The result was disbonding of the topcoat

Fig. 1 Interiors of H-53 helicopter showing fungal growth on polyurethane painted surfaces. (a) Overview. (b) Detail of cable penetration

(Fig. 2), with no corrosion of the base metal as long as the primer was intact. The biocidal properties of zinc chromate primer (Ref 6) were documented. None of the isolates in the study detailed in Ref 5 degraded the polyurethane coating directly as a sole source of nutrients; however, all grew on hydraulic fluid that accumulated on painted interiors during routine operations. Glossy finish polyurethane was colonized more rapidly than the same formulation with a flat finish. Aged paint fouled more rapidly than did new coatings. Laboratory tests demonstrated that in the presence of hydraulic fluid, all of the isolates caused localized corrosion of bare 2024 aluminum. It was demonstrated (Ref 5) that performance specification (MIL PRF 85570) for cleaning painted aircraft interiors is effective in removing fungal spores but does not kill fungal cells embedded in the paint. Fungal regrowth was observed within days of cleaning.

Numerous reports document fungal degradation of coatings and, in some cases, corrosion of the underlying metal (Ref 7–9) in atmospheric exposures. It was reported (Ref 10) that ship cargo holds coated with chlorinated rubber and carrying dry cereals and woods were severely corroded within months. Heavy pitting and reduced thickness of the steel plate were observed. Corrosion products were populated with viable fungi. It was demonstrated (Ref 10) that the fungi derived nutrients from degradation of protective coatings in addition to the cargo. Corrosion resulted from acidic metabolic by-products. Deterioration of the epoxy resin coating of ship holds filled with molasses, fatty oils, and other fluid cargoes was reported (Ref 11). Others (Ref 12) studied direct microbial degradation of coatings, such as Buna-N (a polymer of acrylonitrile and butadiene); polyurethane (a carbamate polymer); and a polysulfide. They found that both bacteria and fungi could degrade these coatings. Pitting of the underlying metal coincided with blisters and the presence of microorganisms. It was demonstrated (Ref 13) that malfunctioning of M483 155-mm howitzer shells stored in humid environments was directly related to fungal degradation of the lubricating grease used to facilitate the screw connection between the base and the body of the shell.

Indirect dissolution of protective greases by fungi was investigated (Ref 14). Protective greases are used to provide corrosion protection for seven-strand carbon steel cable used as wire rope and as highlines. Each cable is made of six strands wrapped around a central core. When cable is used as rope or highline, the cable is coated with thick maintenance grease, threaded onto wooden spools (Fig. 3a–c), and wrapped in brown paper and black plastic. The maintenance grease is applied to the cable to provide corrosion protection. Wire rope is stored on wooden spools for weeks to months before being used. In an investigation of localized corrosion on wire rope stored on wooden spools, fungal growth was observed on interiors of some wooden spools stored outdoors. Corrosion was most severe on wraps of wire in direct contact with the wooden

spool flanges. *Aspergillus niger* and *Penicillium* sp. were isolated from wooden spool flanges (Fig. 4). Fungal isolates could not grow on the protective grease as the sole nutrient source. The isolates grew on wood and produced copious amounts of acids and CO₂. In all cases, localized corrosion was observed in areas where acidic condensate dissolved the maintenance grease and exposed bare areas of carbon steel.

Researchers (Ref 15) determined that 80% of lubricants used for protecting materials were contaminated with 38 biological agents (21 fungi

and 17 bacteria) during storage and use, independent of climate or relative humidity. They identified the following species as those most frequently isolated from lubricating oils: *Aspergillus versicolor*, *Penicillium chrysogenum*, *Penicillium verrucosum*, *Scopulariopsis brevicaulis*, *Bacillus subtilis*, and *Bacillus pumilis*. Microorganisms isolated from one particular lubricant could not always grow vigorously on others. Microbial growth in lubricants was accompanied by changes in color, turbidity, acid number, and viscosity. Acid number refers to the acid or base

composition of lubricating oils and is also referred to as corrosion number. Biocides, including 4-caproyl, have been evaluated as additives to protect lubricants from mold formation. Biocides have limited lifetimes and limited effectiveness (Ref 16).

Metals Exposed to Hydrocarbon Fuels

One of the most persistent corrosion problems throughout the military is the result of microbial contamination and decomposition of hydrocarbon fuels during fuel transportation, storage, and use. Microbial interaction with hydrocarbon fuels is limited to water availability. Water is sparingly soluble in hydrocarbons. Therefore, microbial growth in hydrocarbons is concentrated at oil/water interfaces, emulsified water, and in separate water phases. The volume of water required for microbial growth in hydrocarbon fuels is extremely small. Because water is a product of the microbial mineralization of organic substrates, it is possible for microbial mineralization of fuel to generate a water phase for further proliferation. For example, *Hormoconis resinae*, the kerosene fungus, grew in 80 mg water per liter of kerosene, and after four weeks' incubation, the concentration of water increased more than tenfold (Ref 17).

The first step in microbial decomposition of hydrocarbons is an aerobic process that requires molecular oxygen. Researchers (Ref 18) compared degradation of hydrocarbons by bacteria and fungi. Bacteria showed decreasing abilities to degrade alkanes with increasing chain length. Filamentous fungi did not exhibit a preference for specific chain lengths. The first products of microbial oxidation of hydrocarbons are alcohols, aldehydes, and aliphatic acids.

An increase in the corrosivity of jet fuel (JP4) stored underground in unlined rock caverns in

Sweden caused by sulfate-reducing bacteria (SRB) was documented (Ref 19). Several authors have documented the problem of MIC in aircraft fuel tanks. It was proposed (Ref 20, 21) that microorganisms influenced corrosion of aluminum fuel tanks by:

- Removing corrosion inhibitors, including phosphate and nitrate, from the medium
- Producing corrosive metabolites
- Establishing microcenters for galvanic activity, including oxygen concentration cells
- Removing electrons directly from the surface of the metals

Several investigators reported a decrease in bulk fuel pH due to metabolites produced during growth of fungi (Ref 21–25). One researcher (Ref 24) demonstrated a correlation between growth of *Cladosporium* (*Hormoconis*) and pH at fuel/water interfaces and measured pH values between 4.0 and 5.0 in the fuel. Fungal-influenced corrosion has been reported for carbon steel and aluminum alloys exposed to hydrocarbon fuels. Another investigator (Ref 22) demonstrated metal ion binding by fungal mycelia, resulting in metal ion concentration cells on aluminum surfaces. It was reported (Ref 24) that corrosivity increased with contact time due to accumulation of metabolites under microbial colonies attached to metal surfaces. Others (Ref 25) demonstrated that the metabolic products enhanced aqueous phase aggressiveness even after the life cycle of *Cladosporium* (*Hormoconis*) was completed.

Microbiologically influenced corrosion has been identified in engines, holding tanks, skags, and oily waste tanks on surface ships due to microorganisms growing in water contaminated hydrocarbons. One study (Ref 26) determined that ship engine malfunction and corrosion were associated with MIC. The researchers identified both bacteria and fungi growing in engine lubricants and attributed the problem to a combination of mechanisms, including depletion of protective additives, acid production, and sulfide production. Progressive changes in the formulations of lubricating oils have introduced nitrogen, phosphorus, and sulfur which provide required nutrients for microbial growth. The current trend to produce environmentally benign engine oils means that the resulting formulations are more readily biodegraded. Slow-speed marine engines are at risk because they run for long periods of time at constant temperatures (37 to 55 °C, or 99 to 131 °F) conducive to microbial growth. Oil additives that encourage microbial growth include (Ref 26):

Metal soaps, e.g., barium sulphonates
 Polyalkenyl succinimides
 High-molecular-weight carboxylic acids
 Metal dithiophosphates
 Polyorganosiloxanes
 Hindered phenols, e.g., 2,6 ditertiary butyl-4-methyl phenol
 Aromatic amines-phenyl B naphthylamine
 Alkyl phosphates
 Alkyl-Aryl phosphates, e.g., tricresyl phosphate

Immersion

Immersion environments are those in which the surface is boldly exposed to an aqueous environment, in contrast to the previous examples in which water was the limiting factor for microbial growth. The most important factor controlling the distribution of microorganisms in immersion environments is the availability of nutrients. For example, organic nutrients and bacteria are most abundant in the upper layers of oceans, and both decrease with depth (Ref 27). Microbial biofilms develop on all surfaces in contact with aqueous environments (Ref 28). Chemical and electrochemical characteristics of the substratum influence biofilm formation rate and cell distribution during the first hours of exposure. Electrolyte concentration, pH, organic, and inorganic ions also affect microbial settlement. Biofilms produce an environment at the biofilm-surface interface that is radically different from that of the bulk medium in terms of pH, dissolved oxygen, and inorganic and organic species. In some cases, the presence of localized microbial colonies can cause differential aeration cells, metal concentrations cells, and under-deposit corrosion. In addition, reactions within biofilms can control corrosion rates and mechanisms. Reactions are usually localized and can include:

- Sulfide production
- Acid production
- Ammonia production
- Metal deposition
- Metal oxidation/reduction
- Gas production

Many of the problems of MIC of military assets exposed to aqueous environments are directly related to an operational mode that includes periods of stagnation. Heat exchangers, fire protection systems, holding tanks, and transfer lines are exposed to flow/no-flow cycles. The following statements are applicable for distilled/demineralized, fresh, estuarine, and marine waters. During stagnation, naturally occurring microorganisms form a biofilm, and aerobic microorganisms use the dissolved oxygen as the terminal electron acceptor. If the rate of respiration is faster than the rate of oxygen diffusion through the biofilm, the metal/biofilm interface becomes anaerobic, allowing anaerobic bacteria to produce corrosive metabolites, including acids and sulfides. The amount of sulfide that can be produced within a biofilm depends on the sulfate concentration and the numbers and activities of SRB. Seawater contains approximately 2 g/L of sulfate and a population of SRB whose numbers vary with nutrient concentration. Most sulfide films are not tenacious and are easily removed by turbulence. Introduction of flowing oxygenated water causes oxidation and/or disruption of surface deposits formed under stagnant conditions.

Copper alloys have a long history of successful application in seawater piping systems

Fig. 4 Fungi (white spots) growing on inside flange of wooden spool.

due to their corrosion resistance, antifouling properties, and mechanical properties. The corrosion resistance of copper in seawater is attributable to the formation of a protective film that is predominantly cuprous oxide, irrespective of alloy composition (Ref 29). Copper ions and electrons pass through the film. In seawater, copper ions dissolve and precipitate as $\text{Cu}_2(\text{OH})_3\text{Cl}$ (Ref 30). Copper seawater piping systems are often exposed to polluted harbor water containing sulfides. In the presence of sulfides, copper ions migrate through the layer, react with sulfide, and produce a thick black scale. Failure of copper-nickel pipes in estuarine and seawaters can be associated with waterborne sulfides that stimulate pitting and stress corrosion cracking (Ref 31–34). 90Cu-10Ni suffered accelerated corrosion attack in seawater containing 0.01 ppm sulfide after a one day exposure (Ref 35). Galvanic relationships between normally compatible copper piping and fitting alloys become incompatible after exposure to sulfide-containing seawater (Ref 33).

Sulfides produced within biofilms have the same effect as waterborne sulfides on copper alloys. Alloying additions of nickel and iron into the highly defective p-type Cu_2O corrosion product film alters the structure (Ref 29) and results in a film that possesses low electronic and ionic conductivity. In an attempt to prevent sulfide-induced corrosion of copper-nickel piping, FeSO_4 treatments were evaluated. Corrosion of FeSO_4 -treated pipes was compared with untreated pipes that had been cleaned according to military specifications (Ref 36). Batch FeSO_4 treatments did not result in a persistent increase in surface-bound iron. The authors found that the dissolved iron concentration in most harbor waters exceeded the amount of iron in the recommended batch FeSO_4 treatments. Ferrous sulfate (0.10 mg/L ferrous ion) treatments for 90Cu-10Ni and 70Cu-30Ni alloys were evaluated (Ref 37). Neither pretreatment before sulfide exposure nor intermittent treatment during sulfide exposure significantly reduced sulfide attack on either alloy. However, continuous treatment eliminated the attack on both alloys because the FeSO_4 removed sulfides from solution.

Nickel Alloys. Nickel 201, sometimes used for heat exchangers with distilled water, is vulnerable to microbiologically produced acids (Ref 38). The Ni-Cu alloys are used in seawater under conditions including high velocity (propeller shafts, propellers, pump impellers, pump shafts, and condensers), where resistance to cavitation and impingement is required. Under turbulent and erosive conditions, nickel-copper alloys are superior to predominantly copper alloys because the protective surface film remains intact. Nickel alloys are used extensively in highly aerated, high-velocity seawater applications. The formation of the protective film on nickel is aided by the presence of iron, aluminum, and silicon. However, under stagnant seawater conditions, nickel-copper alloys are susceptible to pitting and crevice corrosion

attack where chlorides penetrate the passive film (Ref 39). Sulfides produced by SRB cause either a modification or breakdown of the oxide layer and dealloying (Ref 40). Another report (Ref 41) indicated that predominantly nickel alloys were susceptible to underdeposit corrosion and oxygen concentration cells. Other studies (Ref 42, 43) demonstrated pitting and denickelification of nickel-copper tubes exposed in Arabian Gulf seawater with deposits of SRB.

Stainless Steels. The corrosion resistance of stainless steel is due to the formation of a thin passive chromium-iron oxide film. Crevice corrosion is the most problematic issue affecting the performance of stainless steels in seawater. Investigators (Ref 44) studied crevice corrosion of stainless steel beneath dead barnacles and proposed the following scenario:

- Decomposition of the barnacle by aerobic bacteria, including *Thiobacillus*, reduces pH within the barnacle shell.
- The acid penetrates the shell base and initiates a corrosion cell between the crevice area and the exposed SS substratum.
- Crevice corrosion initiates near the edge of the shell base and propagates inward.

Crevice corrosion is exacerbated in warm natural seawater where biofilms form rapidly. Pit propagation under barnacles is assisted by poor water circulation.

Several investigators (Ref 45–52) have documented the tendency for biofilms to cause a noble shift, or an ennoblement, in open-circuit potential of passive alloys exposed in marine environments. Alloys tested include, but are not limited to: UNS S30400, S30403, S31600, S31603, S31703, S31803, N08904, N08367, S44660, S20910, S44735, N10276, and R50250. The practical importance of ennoblement is increased probability of localized corrosion as E_{corr} approaches the pitting potential (E_{pit}) for stainless steels vulnerable to crevice corrosion, especially types 304 (UNS S30400) and 316 (UNS S31600). Investigators (Refs 53, 54) concluded that biofilms increased the propagation rate of crevice corrosion for UNS S31603, S31725 and N08904 by 1 to 3 orders of magnitude. They attributed ennoblement to an increase in kinetics of the cathodic reaction by the biofilms. Others (Ref 55, 56) demonstrated that ennoblement of electrochemical potential in the presence of a biofilm could be reconciled without reference to modified oxygen reduction mechanisms and without enhancement of cathodic processes. They concluded that the biofilm does not directly affect oxygen reduction near the equilibrium potential and far from the oxygen diffusion limiting current. They further concluded that H_2O_2 and manganese oxides did not play a direct role in the oxygen reduction process at potentials $> 300\text{mV}_{\text{SCE}}$. Instead, they demonstrated that anodic oxidation of organic material in biofilms produced currents corresponding to passive currents or higher. Oxidation of organic material affects the value of the

corrosion potential and lowers the pH at the surface.

One of the most common forms of MIC attack in austenitic stainless steel is pitting at or adjacent to welds. The following observations were made for MIC in 304L (UNS S30403) and 316L (UNS S31603) weldments (Ref 57): both austenite and delta ferrite phases may be susceptible; and varying combinations of filler and base materials failed, including matching, higher-, and lower-alloyed filler combinations. Microsegregation of chromium and molybdenum with chemically depleted regions increases susceptibility to localized attack.

Candidate materials for a double hull vessel designed with permanent water ballast, 316L, Nitronic 50 (UNS S20910), and AL6XN (N08367) were evaluated for potential MIC in flowing and stagnant freshwater and seawater (Ref 58). No pitting was observed in AL6XN under any exposure condition after one year. Leaks were located at weld seams of Nitronic 50 and 316L stainless steels after 6 and 8 week exposures to stagnant and flowing seawater. A failed vertical weld in 316 stainless steel after an 8 week exposure to stagnant natural seawater is shown in Fig. 5(a). Figure 5(b) is the corresponding x-ray image indicating failure due to pitting. In all cases, large numbers of bacteria were associated with the corrosion products (Fig. 5c). Residual material in pits was typical of removal of iron. A scanning vibrating electrode technique was used to demonstrate that there were no persistent anodic sites in autogenous welds or heat affected zones of these materials exposed to sterile seawater. The spatial and causal relationship between bacteria and pitting in weldments in 300 series stainless steels is well documented (Ref 59, 60).

Ethylene glycol/water and propylene glycol/water mixtures were evaluated as permanent ballast waters for 316L double hull vessels (Ref 60). The compounds are attractive as ballast liquids because they will have minimal impact if the outer hull is breached and the glycols are released to the environment. Both have low volatility and are miscible with water. In terms of corrosion protection, propylene glycol-based mixtures were shown to protect against pitting of 316L in concentrations of 50% or higher when mixed with seawater (3.5% salinity). Slightly higher concentrations (55%) of ethylene glycol-based mixtures were required under the same conditions to prevent pitting. The compounds have little or no capacity to bind to particulates and will be mobile in soils or sediments. Glycol-based mixtures were also shown to be bacteriostatic at concentrations above 10%. Also, the low octanol/water partition coefficient and measured bioconcentration factors in a few organisms indicate low capacity for bioaccumulation.

Carbon Steel. Unexpectedly rapid localized corrosion of steel bulkheads and ship hull plating of tankers in marine harbor environments was documented (Ref 61). In each case, the localized attack was found beneath macrofouling layers. The biofilm at and around the corrosion sites was

Fig. 5 Vertical weld in 316 stainless steel after exposure to stagnant natural seawater for 8 weeks. (a) Weldment. (b) X-ray of failed vertical weld. (c) Bacteria associated with corrosion products.

populated with a rich consortium of aerobic and anaerobic microorganisms, and the SRB population was elevated by several orders of magnitude above that in the biofilm remote to corrosion sites. Researchers (Ref 62) demonstrated a cycle of sulfur oxidation and reduction causing aggressive corrosion of steel pilings in a harbor. At low tide, the fouling layer was thoroughly aerated and thiobacilli produced oxidized sulfur species. High tide produced anaerobic conditions within the fouling layers and reduction of sulfur compounds.

Natural seawater has also been evaluated as a ballast fluid in unpainted 1020 carbon steel ballast tanks, and deoxygenation has been proposed as a method to reduce corrosion. However, it was determined (Ref 63) that corrosion of 1020 carbon steel coupons in natural seawater over a six month period was more aggressive under stagnant anaerobic conditions than stagnant aerobic conditions as measured by weight loss and instantaneous corrosion rate (polarization resistance) (Fig. 6). Under oxygenated conditions, a two-tiered oxide layer formed (Fig. 7a). The outer oxide layer was reddish-brown and contained numerous filamentous bacteria (Fig. 7b). The inner oxide was extremely adherent and resistant to acid cleaning. Under anaerobic conditions, a nontenacious sulfur-rich corrosion product with enmeshed bacteria formed on carbon steel surfaces (Fig. 7c, d). In anaerobic exposures, corrosion was more aggressive on horizontally oriented coupons compared with vertically oriented coupons. Bulk

water chemistry and microbial populations were measured as a function of time. Both were dynamic despite the stagnant conditions.

Cathodically Protected Carbon Steel. In most cases, carbon steel used in seawater is cathodically protected or painted. It has been reported that cathodic protection retards microbial growth because of the alkaline pH generated at the surface. It was demonstrated (Ref 64) that a potential of -1.10 V SCE markedly decreased settlement of *Balanus cyprids* on painted steel surfaces, but it had no effect on settlement, sand-tube building, reproduction, or larval release of other species. Biofouling in seawater was retarded using pulsed cathodic polarization of steel (Ref 65).

Numerous investigators have demonstrated a relationship between marine fouling and calcareous deposits on cathodically protected surfaces (Ref 66–68); however, their interrelationships are not understood. Microbiological data for cathodically polarized surfaces are often confusing and impossible to compare because of differing experimental conditions (laboratory vs. field) and techniques used to evaluate constituents within the biofilm. Differences in organic content of seawater that produced differences in current density, electrochemistry, calcareous deposits, and biofilm formation have been reported (Ref 66).

The influence of a preexisting biofilm on the formation of calcareous deposits under cathodic protection in natural seawater was studied (Ref 67). It was shown that applied current

densities up to $100 \mu\text{A}/\text{cm}^2$ did not remove attached biofilms from stainless steel surfaces. Both natural marine and laboratory cultures changed the morphology of calcareous deposits formed under cathodic polarization at a current density of $100 \mu\text{A}/\text{cm}^2$.

In one study (Ref 69), cathodic potentials to -1000 mV SCE caused a decrease in pH and an increase of SRB on carbon steel. At potentials more negative than -1000 mV SCE, the pH became more alkaline and SRB numbers decreased. A study of the influence of SRB in marine sediments using electrochemical impedance spectroscopy to monitor corrosion and lipid analysis as biological markers, complemented by chemical and microbiological analysis, showed that -880 mV SCE encouraged the growth of hydrogenase-positive bacteria in the sediment surrounding the metal and facilitated the growth of other SRB species (Ref 70).

Because the enumeration technique strongly influences the number of cells one is able to count, and because the number of cells cannot be equated to cellular activity, including sulfate reduction, some investigators have attempted to measure cellular activity directly on cathodically protected surfaces. One investigator (Ref 71) cathodically protected 50D mild steel (BS 4360) coupons exposed in the estuarine waters of Aberdeen Harbor using an imposed potential of -950 mV Cu:CuSO₄ and sacrificial anodes. Activities within biofilms were determined using a radiorespirometric method—a technique for studying microbial respiration using

Fig. 6 Instantaneous corrosion rates using polarization resistance (R_p) for carbon steel exposed in stagnant aerobic or stagnant anaerobic natural seawater. Corrosion rates were higher for the anaerobic exposures (solid lines) than for aerobic exposure (broken lines). R1, R2, R3, and R4 refer to the vertical location of the electrode, with R1 being closest to the water surface and R4 located at the bottom of the experimental chamber.

Scanning electron micrograph of sulfide-encrusted organisms enmeshed in corrosion products.

radiolabeled substrates or electron acceptors. Biofilms developed on all substrata—both unprotected and cathodically protected surfaces. The activities of aerobic and anaerobic bacteria, including SRB, were significantly greater on unprotected coupons. Furthermore, sulfide, a metabolic fingerprint of SRB activity, could be detected only in biofilms on unprotected coupons. These results show that a potential of -950 mV Cu:CuSO₄ does not prevent SRB from developing on cathodically protected surfaces. The lower activity of SRB within biofilms on cathodically protected coupons was not directly caused by any inhibitory effect of the cathodic potential. Instead, the greater activity of SRB on unprotected coupons was the result of production of an extensive corrosion film offering more favorable anaerobic conditions.

The NACE Standard (Ref 72), which is currently under revision, lists cathodic protection criteria for underground or submerged steel, cast iron, aluminum, and copper structures. Microbiologically influenced corrosion is cited as “one of several abnormal conditions which sometimes exist and where cathodic protection is ineffective or only partially effective.” It is important to point out that in several studies (Ref 66–68), SRB were present on cathodically protected steels, but accelerated corrosion was not reported.

Thermodynamic data with iron in a pH 7 electrolyte saturated with hydrogen sulfide was studied (Ref 73). A potential of -1024 mV SCE was required to achieve cathodic protection. It was demonstrated (Ref 74) that -1024 mV was capable of providing cathodic protection in the presence of active SRB. The influence of cathodic protection on the growth of SRB and on corrosion of steel in marine sediments was investigated (Ref 75). The investigators concluded that a cathodic potential of -880 mV SCE did not appear to be sufficient for protection and that large amounts of cathodically produced hydrogen promoted the growth of SRB in the sediments surrounding the samples. Laboratory tests were conducted (Ref 76) in anaerobic, artificial sediments containing SRB. Results indicated that a polarization of -1024 mV SCE was adequate for corrosion protection. Cathodic protection current density was between 4.5 and 12 mA/ft². Another study (Ref 77) indicated that a cathodic potential of -1054 mV SCE lowered the corrosion rate of steel by 82.7%, even though protective potentials in the range -774 to -1134 mV SCE did not inhibit growth of SRB. It was concluded (Ref 78) that if anaerobic bacterial activity is suspected, a cathodic polarization shift of approximately 200 to 300 mV SCE is required for carbon steel protection. Cathodic protection was imposed on steel surfaces actively corroding in cultures of SRB (Ref 79), and it was concluded that cathodic protection in the presence of SRB decreased corrosion by a factor of 8 or 9.

It was shown (Ref 80) that cathodically protected stainless steel surfaces in artificial seawater can become colonized by aerobic,

acid-producing bacteria. Formation of calcareous deposits and initial settlement of microorganisms resulted in decreased current density requirements to maintain a protection potential. Subsequent colonization and pH changes destabilized the calcareous deposits and dramatically increased the current density required to maintain the protected potential.

Hydrogen embrittlement of carbon steel is a form of corrosion involving the cathodic reaction. Atomic hydrogen generated in the cathodic reaction penetrates the steel resulting in the loss of ductility. A number of mechanisms have been postulated to account for the embrittlement effect, which, when combined with the presence of local regions of high stress, can result in severe cracking (Ref 81). Hydrogen embrittlement is enhanced by the high levels of hydrogen generated by SRB under certain conditions, as well as that generated by overly aggressive cathodic protection systems. If the levels of cathodic protection are increased too high to combat SRB corrosion, there is a danger that hydrogen embrittlement may be enhanced. The presence of H_2S , which can be produced by SRB, is known to retard formation of molecular hydrogen on the metal surface and to enhance adsorption of atomic hydrogen by the metal. Whenever algae provide conditions for SRB, they may also enhance hydrogen embrittlement.

In summary, bacteria can settle on cathodically protected surfaces. Cathodic potentials to -1074 mV SCE do not prevent biofilm formation. It has been suggested that actual cell numbers may be related to polarization potential, dissolved organic carbon, or to the enumeration technique. Numbers of SRB may be increased or decreased depending on exposure conditions. Carbon steel is considered protected when a potential of -924 mV SCE is achieved. In many cases, the potential is further reduced to -1024 mV SCE to protect the steel from corrosion caused from the activity of SRB. The decreased potential is not applied to prevent growth of SRB but is based on a theoretical level that will allow passivity of steel in a sulfide-rich environment produced by SRB. The main consequence of biofilm formation on protected surfaces appears to be an increase in the current density necessary to polarize the metal to the protected potential. The presence of large numbers of cells on cathodically protected surfaces does mean that in the event that cathodic protection is intermittent, discontinuous, or discontinued, the corrosion attack due to the microorganisms will be more aggressive.

Coated Carbon Steel. Although coatings alone do not prevent MIC, they delay the onset of MIC and other corrosion reactions. Many types of polymeric coatings can be subject to biodegradation. The attack is usually caused by acids or enzymes produced by bacteria or fungi. This often results in selective attack on one or more specific components of a coating system with consequent increase in porosity and water or other ion transport through the coating and the formation of blisters, breaches, and disbonded

areas. Many of these effects have recently been reviewed (Ref 82). It was also demonstrated (Ref 83) that marine bacteria are attracted to corrosion products at coating defects. The microorganisms responsible for damage to coatings may or may not be involved in corrosion initiation under the damaged coating.

Titanium and Titanium Alloys. There are no case histories of MIC for titanium and its alloys. One investigator (Ref 84) reviewed mechanisms for MIC and titanium's corrosion behavior under a broad range of conditions. He concluded that at temperatures below $100^\circ C$ ($212^\circ F$) titanium is not vulnerable to iron/sulfur-oxidizing bacteria, SRB, acid-producing bacteria, differential aeration cells, chloride concentration cells, and hydrogen embrittlement. In laboratory studies, (Ref 85) corrosion of Grade 2 titanium (UNS 850400) was not observed in the presence of SRB or iron/sulfur-oxidizing bacteria at mesophilic ($23^\circ C$, or $73^\circ F$) or thermophilic ($70^\circ C$, or $158^\circ F$) temperatures. Using the model in Ref 86, one would predict that titanium would be immune to SRB-induced corrosion. There are no standard free energy reaction data for the formation of a titanium sulfide. If one assumes a hypothetical sulfide product to be titanium sulfide, the standard enthalpy of reaction is $+587$ kJ. While standard free energies of reaction are not identical to standard enthalpies of reaction, it is still unlikely that titanium will be converted to the sulfide under standard conditions of temperature and pressure.

Aluminum alloys were evaluated (Ref 87) for the impact of microorganisms on corrosion of aircraft in bilge and toilet areas. The researchers isolated numerous microbiological species and were able to cause corrosion of 7075, which is used in aircraft construction. However, the authors could not relate their experiments to actual aircraft.

Polymeric Composites. Microorganisms and their products can be responsible for changes in physical, chemical, and electrochemical properties of polymeric materials. Reference 88 demonstrated that under immersion conditions, epoxy and nylon coatings on steel were breached by mixed cultures of marine bacteria.

In laboratory experiments (Ref 89), it was demonstrated that epoxy resin and carbon fibers, either individually or in composite, were not degraded by sulfur/iron-oxidizing, hydrogen-producing, calcareous depositing, or SRB. Bacteria colonized resins, fibers, and composites but did not cause damage. Sulfate-reducing bacteria preferentially colonized vinyl ester composites at the fiber-resin interfaces, and hydrogen-producing bacteria appeared to disrupt the fiber-vinyl ester resin bonding with penetration of the vinyl ester resin.

It is standard practice to coat the surface of the filaments with a sizing chemical to provide a better bonding with the resin matrix and to prevent abrasion between individual fibers during shipping and handling. This treatment permits optimal stress transmission between filaments. Fiber sizing chemicals are starch-oil mixtures.

The sizing materials are highly susceptible to biodegradation of strength resulting from abrasion between fibers and as a coupling agent to the matrix. The sizing materials are highly susceptible to biodegradation and can be expected to decompose in the presence of contaminating microorganisms (Ref 90).

Researchers (Ref 91, 92) investigated fungal degradation of polyimides used as insulators in electronic packaging. Growth of microorganisms on these polymers was found to result in loss of their dielectric properties. They also studied biodeterioration of fiber-reinforced composites, graphite sheets, and graphite fibers used in composite materials. They observed fungal penetration into composite resin and graphite sheets and concluded that fungi caused substantial damage to composites under conditions favorable to fungal growth. Investigators (Ref 93) demonstrated in the laboratory that mixed cultures of marine bacteria could penetrate three conductive caulks (PRC 1764, PI8500, and PI8505) used to secure antenna foundations to ship superstructures.

Burial Environments

Tapes and coatings for buried pipes and cables are susceptible to biodegradation and MIC (Ref 94). A recent study evaluated the potential for MIC of unexploded ordnances (UXO) buried in soil environments. Unexploded ordnances are military munitions that have been prepared for action but remain unexploded and constitute a potential hazard. The 1998 Defense Science Board estimated 1,400 individual sites contained UXO (Ref 95). The munitions corrode at varying site-specific corrosion rates. In most subsurface environments, microbial growth is limited by water. The likelihood that MIC will take place is directly related to water availability. Microorganisms concentrate at interfaces, including soil/surface interfaces. A survey determined that the microbial populations measured on the surface of UXO were sufficient to cause localized corrosion and that the most likely mechanism was microbial acid production. Microbially induced corrosion of carbon steel is independent of pH over pH values 4.5 to 9.5. In this range, the corrosion products maintain a pH of 9.5 next to the steel surface, regardless of the pH of the solution. At a pH of 4 or below, hydrogen evolution begins and corrosion increases rapidly. Fungi and acid-producing bacteria can reduce the pH locally to values below 4.0. The localized corrosion mechanism of the steel fragments was in many cases pitting, with pits inside pits, indicating multiple initiation sites. In other cases, tunneling was observed. Both types of localized corrosion are consistent with microbiological acid-induced corrosion.

Service Life and Aging of Military Equipment

M. Colavita, Italian Air Force

MILITARY SYSTEMS AND EQUIPMENT are designed to have a certain service life and to perform one or more specific functions over a specified length of time or, in the case of one-shot devices, be capable of performing a function after storage or within a specific time interval after manufacture when operated and maintained according to some stated plan. Service life extension and aging of military systems are a continuously growing problem (Ref 1). The combination of shrinking post Cold War military budgets and escalating costs for development and acquisition of new military equipment have led to increasing efforts worldwide to extend the operation of the existing systems far beyond their original design lives (Ref 2, 3). This article is mainly devoted to aircraft, but most of the considerations and the criteria exposed can be extended to land and sea vehicles.

In a general sense, aging vehicles are characterized by the deterioration of structural strength properties and increasing maintenance costs (Ref 4, 5), whose common effect is to reduce the readiness of the vehicle (Ref 6). Some of these problems are time dependent, such as corrosion, which also depends heavily on the usage environment; others are usage dependent, such as in fatigue cracking, which is caused by the mechanical loads that are introduced into the structure, and also in electronic devices. Intermediate conditions are often met and the strong correlation existing between corrosion and fatigue must always be taken into account. A schematic representation of this correlation is given in Fig. 1. The accelerating effect on corrosion damage due to cracking is shown (Ref 7). Corrosion that starts acting after a given initial time (t_i) (e.g., due to coating breakdown) instead of following its natural rate trend (dashed line), strongly increases in the presence of a crack (curve AC); the synergic effect given by the combination of these two elements—corrosion and cracking—is also shown by the shift of the damage curve toward shorter time (from AC to AB) when the environment inside the crack moves from inert to aggressive.

To maintain structural integrity, steps must be taken toward the prevention, detection, repair,

and prediction of the initiation and growth of structural damage (Ref 8). This matter is a frontier between safety and economy issues, and every evaluation must be carefully appraised in terms of risks and benefits. Otherwise the short-term cost savings will be offset by greater long-term costs, safety problems, or decreased system availability.

The primary focus is to maintain operational military capability by directing resources toward high payback technologies able to:

- Identify structural deterioration
- Prevent the threat to equipment safety or performance degradation and minimize structural deterioration
- Avoid the system becoming an excessive economic burden or adversely affecting force readiness
- Assist in replacement of components
- Assist in development of failure analysis and life-predictive tools for such problems as fatigue damage, corrosion, and stress-corrosion cracking

Taking into account that a uniform in-service life for all equipment components in an aged system is not achievable, it is therefore very important to record in-service operational and maintenance data for critical equipment in order to be able to assess the usage history and life consumption and define the point of retirement.

Reliability and Safety of Equipment

In agreement with the usual behavior of the expected failure for any population of mechanical or electronic devices, the reliability of equipment with time is defined by the curve in Fig. 2, widely known as the “bathtub curve” because of its shape (Ref 9). In particular, the reliability decreases as the rear field of the curve (wear-out) is achieved. This occurs because malfunctions caused by aging and/or wear increase. In this way, the spare part demand and the number of maintenance actions increase,

which consequently result in higher operating costs and reduced availability.

A typical measure within a life-extension program would determine the optimal point of time when it would be more economical to replace an item with a new part or to introduce redesign or an upgrade instead of repairing the old item again and again.

It is important to include preventive maintenance actions for critical components and areas in the existing maintenance procedures to ensure that aging problems will be detected at an early stage (Ref 10) when the amount of effort required for repair is still acceptable and a safety critical situation is avoided.

Mainly, reliability of an aged component depends on several factors such as its usage history, repairs and life-extension concessions, obsolescence, availability of spare parts, and failure data already available.

Aging Mechanisms

Aging is a process where the structural and/or functional integrity of components will be continuously degraded by exposure to the environmental conditions under which it is operated. There are various mechanisms that alone, or in

Fig. 1 Growth of corrosion and fatigue cracking with time

combination, are responsible for component aging:

- The exposure to normal or salty atmospheres, heat, water, oil, fuel, and so forth, which could lead to corrosion, overheating, melting, disbonding, or other material degradation processes, electrical interruptions, short circuits, and so forth
- The exposure to vibration and acoustic environments, which could lead to fatigue damages, wear, tear, and so forth
- The endurance to normal service conditions, which leads to leakage, wear, tear, and so forth

Additionally, improper installation of equipment, or incorrect maintenance activities, also can induce accidental damage or have a detrimental effect and assist the aging process, for example, scouring of wire bundles on the surrounding structure.

Factors that have a direct effect on the problems associated with military system aging

are its usage, the service environment, and the inspection, test, and maintenance practices. In particular, the location of the equipment will determine corrosion problems (Ref 11). For example, military aircraft that are exposed to salt water environments, as on an aircraft carrier deck, will experience a much higher degree of corrosion than other military aircraft. The predisposition to corrosion also depends on factors such as corrosion resistance of the material, combination of materials, and surface protection and sealing.

Structural Parts

Corrosion usually plays the most important role in the degradation with time of structural components. Many types of corrosion can occur in military structures, but the general attack occurring on the surfaces in reciprocal contact of splice joints (faying surfaces) is probably the process most often observed on aged parts. It usually occurs when adhesive bond or sealant

between the layers breaks down, allowing moisture ingress. Depending on the severity of the attack and the material corrosion resistance characteristics, it can then develop or be accompanied by pitting or exfoliation. The final effect of this degradation process is a reduction of the mechanical properties of the part, in particular of the fatigue life of the joint (Fig. 3, 4).

Another class of damage produced by corrosion of splice joints is "pillowing cracks," an environmentally assisted form of failure under sustained stress due to the deformation of the layers of the joint between the fasteners. It is caused by the increase in volume associated with aluminum alloy corrosion products. This volume increase was recently estimated at 6.45 (molecular volume ratio) times the volume of the parent material lost (Ref 12). This volume increase results in a significant increase in the stress in the vicinity of the rivet holes and is believed to act as a source of the multiside-damage (MSD) whose effects on structural integrity are well known (Ref 13).

In effect, pillowing produces a compressive stress in the rivet area on the outer surface or skin while a high tensile stress is present on the faying surface or inner skin, causing the growth of nonsurface breaking cracks with the suggested shape shown in Fig. 5. This circumstance strongly reduces the probability of detection before first linkup in a MSD situation occurs and therefore significantly increases the risk of an in-service failure. Attempts have been made to quantify this effect by means of mechanistic models (Ref 14), but the many parameters needed render the models unreliable so far, and a more empirical approach continues to be relied upon.

However, the effect of interaction between corrosion and fatigue (Ref 15), one of the main concerns in aging aluminum structures, suggests that some form of hydrogen-related failure is the corrosion mechanism causing environmentally induced cracking in the 2000 and 7000 series aircraft aluminum alloys (Ref 16). Actually, a difference in the effect of preexisting corrosion on fatigue crack initiation and short crack growth on these two alloys has been shown. In the case of 2024-T6, fractographic analysis (Fig. 6) and measured fatigue initiation time indicate that fatigue initiation is primarily a mechanical phenomenon. Corrosion acts as a stress-concentration factor, and geometrical consideration of the corrosion pit can be used to

Fig. 2 Reliability of equipment as defined by the bathtub curve. The infant mortality phase can typically be 20% of useful life.

Fig. 3 Optical micrograph of a high stressed region in a B707 wing panel showing extensive corrosion fatigue cracking

Fig. 4 Scanning electron micrograph of a section through an elongated damage in a B707 wing panel showing corrosion fatigue cracking

Fig. 5 Suggested shape of cracks under influence of pillowing

predict the subsequent fatigue behavior (Ref 17). In the case of alloy 7075-T6, the evidence suggests that other embrittling phenomena may affect the crack growth initiation (Ref 18).

When localized corrosion occurs, an aggressive environment is created inside the pit. The pH will be determined by the hydrolysis reaction $\text{Al}^{3+} + 3\text{H}_2\text{O} \rightarrow \text{Al}(\text{OH})_3 + 3\text{H}^+$, and its usual value will be between 3 and 4. To explain the hydrogen embrittlement mechanism observed for the 7000 alloys, it has been suggested that second-phase particles act as sinks for dislocation transported hydrogen (Ref 19).

Engines

Aging of engine components may take many forms depending on component, engine type, and operating conditions (Ref 20). The damage may be external, affecting dimensions and surface finish as a result of erosion, wear, corrosion,

or oxidation. In this case, the damage affects the aerodynamic performance and load-bearing capacity of gas path components. Additionally, surface cracks and notches induced by low-cycle fatigue (LCF), and fretting and foreign object damage (FOD) may eventually lead to high-cycle fatigue (HCF) failures. The damage may also be internal, affecting the microstructure of highly stressed and hot parts, as a result of metallurgical aging reactions, creep, and fatigue. In this case, the damage may reduce component strength and lead to component distortion. The accumulated damage may cause the initiation of flaws that lead to subsequent cracking and component failure (Ref 21).

Surface Damage. Erosion by ingested sand and other hard particulate matter can significantly alter compressor airfoil shape and surface finish. Such changes, in addition to reducing compressor efficiency, may lead to resonant excitation and HCF failures of

airfoils. Pitting corrosion may develop in marine environments and both steel and titanium alloys are particularly susceptible to this form of damage. Corrosion pits provide sites for crack initiation and have been known to be responsible for HCF failures (Fig. 7).

Surface oxidation reduces the load-bearing capacity of turbine blades and vanes. In marine environments hot corrosion may rapidly destroy airfoils by surface melting, as evidenced by surface rippling (Fig. 8a) and metallographic section (Fig. 8b) for a MAR-M246 nickel-base superalloy turbine blade.

Turbine blades also often suffer tip oxidation, as protective coatings wear off rapidly due to tip rub. In the case of directionally solidified (DS) blades, tip oxidation may produce thermal fatigue cracking at the longitudinal grain boundaries that are embrittled as a result of boundary oxidation (Fig. 9).

Aging associated with fretting has been often observed in the dovetail base where fan and compressor blades come in contact with disks (Fig. 10).

Microstructural Damage. Internal microstructural damage is the result of metallurgical aging reactions and plastic strain accumulation. It is an insidious form of damage because, in contrast with surface damage, it is not readily detected by nondestructive techniques (NDT). Furthermore, its rate of accumulation is strongly influenced by service stresses and temperatures. Since there are uncertainties in the temporal variations of these parameters, the extent of damage accumulation cannot be easily predicted.

Time-dependant aging reactions occur primarily in hot parts, such as turbine blades and vanes; they are varied but invariably detrimental to mechanical properties. Coarsening of γ' precipitates, for instance, causes loss of creep strength in nickel-base superalloys (Fig. 11).

Subsystems

Aging consequences on subsystems are sometimes underestimated with respect to their frequency and relevance. For example, main

Fig. 9 Tip cracking of a directionally solidified MAR-M-246 turbine blade

Fig. 10 Fretting fatigue damage along a titanium fan stage-2 blade dovetail experienced on F-400 engines

Fig. 11 Microstructures of nickel-base Alloy 713C turbine blades. (a) Original structure prior to service. (b) Coarsening of γ' precipitates and elimination of secondary γ' caused by 5000 h of service

landing gears should be carefully considered as one of the weakest points with respect to time-related performances on account of the severity of their service conditions and continuous exposure to harsh environmental conditions.

Catastrophic failures can also be insidiously produced when apparently nondangerous corrosion phenomena are ongoing. This happened in the case of the high-strength steel main landing gear (MLG) truck beam of a B707 tanker, which broke during taxiing (Fig. 12). The final failure was caused by stress-corrosion cracking (SCC) resulting from the high-static stress that the part usually undergoes. However, the original cause was the uniform corrosion phenomenon developed over 35 years of service on the bottom of its internal part, where moisture and humidity had collected (Ref 22). This particular damage was also due to a failure to review appropriate maintenance procedure. The aircraft, originally in civilian use, was maintained in the military on the same scheduled maintenance program, with a consequent large time delay between inspections.

In general, the introduction of materials such as the Aermet 100 Co-Ni low-carbon steel, as an alternative to the more traditional high-strength materials such as AISI 4340 and 300M, should be encouraged in order to increase the safety margin and minimize material sensitivity to hydrogen embrittlement, SCC, and corrosion fatigue (Ref 23).

Wiring is another critical subsystem to be carefully considered in terms of aging behavior. Indeed, greater attention is being paid to this subject since very dangerous failures have occurred (Ref 24). This specific phenomenon is due to a decay of the external insulation that starts cracking with the passage of time and leads to the corrosion of terminal ends (Ref 25). An example of cracked wiring is shown in Fig. 13. Sometimes corrosion occurs under the insulation, especially in the case of aluminum wiring (Ref 26).

In both cases the electrical resistance of the wiring is increased due to the presence of corrosion damage. Deterioration of the electrical

system can cause a number of problems, some of which are extremely difficult to sort out. Corrosion damage can cause erroneous instrumentation readings, including faulty caution and warning indications. It can result in arcing (shorts), either between wires or between wires and the aircraft structure, resulting in fire and smoke.

Management

The management of an aging fleet is a complex task that can be achieved only with actions that include management of corrosion problems. In this sense, the introduction of more effective corrosion preventive measures is a cornerstone of any strategy. Some of the key measures are:

- Improved training in corrosion recognition and treatment
- Wider use of corrosion preventive compounds during regular maintenance
- Washing of aircraft with water containing inhibitors

Full-Scale Structural Testing

Full-scale structural testing is usually done in response to customer mandated requirements at the time of aircraft purchase. Subsequent fatigue improvement modifications are verified by component tests. However, in an aged fleet the discrepancy between tested and current configuration usually becomes too great, dictating the need to update the test database (Ref 27).

Furthermore, to take into account the effects of time on corrosion damage, it is often necessary to evaluate the integrity of the whole structure before extending operational life well beyond the original design life. It means that a renovated full-scale test is needed to verify the actual residual fatigue resistance.

While it is true that the cost of full-scale structural testing often appears prohibitive, the value of the data generated for use in management of service aircraft renders these tests very desirable. They can be summarized as:

- Experimental determination of residual strength of cracked and corroded structures

Fig. 12 Cross section of a stress-corrosion cracking failure occurred on high-strength steel AISI 4340 B707 truck beam, caused by a preexisting uniform corrosion phenomenon

Fig. 13 Wiring insulation cracks (left) and corroded terminals on a C130 (right)

Fig. 14 Stress-corrosion cracking on the Macchi MB-326 7075-T6 stabilizer spar of RAAF aircraft used by the acrobatic team

- Experimental measurement of crack growth curves
- Strain survey verification of the assumed internal loads distribution
- Validation or replacement of the assumed crack location

When these tests are planned, special attention must be focused on sampling. Usually, to be conservative, the oldest aircraft of the fleet—the fleet leader—can be chosen as representative of the worst case. However, because of the primary role played by corrosion, the environment in which the aircraft has been operating throughout its life, the real load spectrum suffered, the maintenance history, and preservation strategies adopted are very important factors to be taken into account. In effect, the same aircraft, when operated by different nations in very different environments and perhaps with different missions will show a widespread range of residual mechanical deterioration properties. An example is the results of tests carried out on a Macchi MB-326 operated as a military trainer by the Italian Air Force (IAF) and in the acrobatic team by the Royal Australian Air Force (RAAF). The strong corrosiveness of the Australian environment resulting from the high salt content, and the

elevated wind in conjunction with the high loads corresponding to the acrobatic use, led to SCC on the 7075-T6 stabilizer spar that did not occur in the Italian fleet (Ref 28). All the observed cracks on the RAAF aircraft initiated along the interior of rivet holes (Fig. 14).

Structure. Risk assessment is certainly one of the most powerful means to manage an aged fleet. It consists of a study of the elements that contribute to the reduction in airworthiness and results in an evaluation based on the acceptable risk. The analysis is founded on a previous knowledge of the degradation mechanisms involved in the aging process. With respect to this point, corrosion data collection has already proved to be an effective tool in risk assessment. Essentially, the complexity of the military systems has encouraged the introduction of appropriate corrosion data banks with two main objectives:

- Increasing the reliability of predictive analysis of failures
- Addressing the resources needed to solve the problems in agreement with a predefined scale of criticalities

The former objective is usually split into two branches, respectively, dedicated to under-

standing of the general trend and introduction of optimized inspection on specific items.

The introduction of corrosion data banks appears promising in both increasing the availability of the fleet and making it easier to achieve standard maintenance procedures among different nations that operate the same fleet.

Engine. For the purpose of life-cycle management, engine components can be classified as either durability-critical or safety-critical parts. The former parts are those for which aging deterioration only affects performance and fuel efficiency, resulting in a significant maintenance burden, but will not directly impair flight safety: they include cold and hot gas path components such as vanes and blades.

The latter parts are those for which fracture may result in loss of the military system and endanger human life because of noncontainment. They include most of the rotating compressor and turbine components such as wheels, disks, spacers, and shafts.

Durability-Critical Parts. These parts employ an “On Condition” maintenance philosophy, which means that a preventative process is used that allows deterioration of components by monitoring them for their continued compliance with a required standard. The parts are removed from service when damage limits exceed those dictated by design.

Safety-Critical Parts. These parts employ two different management approaches.

Safe Life Approach. All components are retired before a first crack is detectable. This methodology follows a “cycles to crack initiation” criterion, with a minimum safe life capability established statistically through extensive mechanical testing of test coupons and components under simulated service conditions. The statistic is based on the probability that 1 in 1000 components (-3σ) will have developed a detectable crack, typically 0.8 mm (0.03 in.) long, at retirement.

This approach is overly conservative, because components are retired with a significant amount of residual life, and its main benefit is that maintenance requirements are kept to a minimum. Under this approach the supply of parts that need to be replaced at the same time may be substantial and this can be a serious problem.

Damage Tolerance Approach. Fracture critical areas of all components are assumed to contain manufacturing or service-induced defects giving rise to growing cracks. In accordance with this approach, components are retired when a crack is detected.

This approach also assumes that components are capable of continued safe operation as the crack grows under service stresses and that the crack growth can be predicted from linear fracture mechanics or other acceptable methods. Of course, it is also required that cracks grow slowly enough to allow their detection through scheduled inspection.

The interval between inspections, or safe inspection interval (SII), is established from the time the crack grows from a size immediately

below the detection limit (it will depend on the technique used to inspect the component) to a critical size. For an assumed geometry, the critical size is obtained by analysis from the fracture toughness of the material and the stress-intensity factor, using appropriate safety factors. This approach is schematically illustrated in Fig. 15, where SII is obtained through the application of either deterministic or probabilistic fracture mechanics (DFM or PFM).

In general terms, two different methods can be used to implement damage tolerance based life-cycle management for safety critical parts: ENSIP (Engine Structural Integrity Program, MIL-STD-1783), introduced in 1984 by the U.S. Air Force (USAF), and RCF (Retirement for Cause), as shown in Fig. 16. The RCF, based on periodic inspections until a crack is detected at which point the part is retired, allows life extension beyond LCF-based safe-life limits.

Practical Life-Enhancement Methods

Structural Parts. Various life-enhancement techniques are already available, some of them being commonly used on operational aircraft (material substitution, cold working, shot peening, and composite patches), and many others are still considered to require engineering supervision (e.g., friction stir welding, grid-lock, laser shock processing, active vibration suppression, laser-formed titanium, etc.).

Material substitution is probably the most common and effective countermeasure to the corrosion effects caused by aging. In effect, new alloys have been developed in the recent past to overcome low corrosion resistance, especially the low SCC resistance characteristic of many older metallic alloys. Typical is the case of aluminum alloy 7055 used to replace 7075, mainly in spar and lugs applications, or all the attempts

made to modify the T6 thermal treatments on this alloy, responsible for its low SCC resistance, but preserving its high strength by retrogression and reaging (RRA) (Ref 29). Another example is the substitution of the current aluminum trailing edge on the C130 that has shown a tendency to corrode and debond from graphite/epoxy panels due to a combination of moisture from the surrounding environment, engine exhaust products, and sonic fatigue.

Fatigue cracks and damage originating at holes are also a strong life-limiting factor, due to the geometric stress-concentration effect that intensifies the magnitude of the applied load by factors of three or more. In this regard, the "hole cold expansion" (Fig. 17) is a practical method to repair corroded or fatigue cracked holes and at the same time to ensure continued airworthiness by inducing beneficial annular residual compressive stresses (Ref 30).

Engines. Life extension can be achieved by means of different strategies (Ref 31):

- Restoration of damaged components by repair or rework (e.g., electron beam weld repair of blades damaged by foreign objects (Ref 32), and weld tip repair of high pressure turbine blades (Ref 33), advanced braze repairs for nozzle guide vanes, and component rejuvenation through hot isostatic pressing)
- Improvement of the structural performance or damage tolerance of engine components, achieved by a range of different techniques, depending on the objective to be accomplished. For example, (a) retrofitting with new materials, when enhancement of component durability in terms of better oxidation behavior, creep strength, or thermal fatigue resistance is required, (b) addition or substitution of a protective coating to improve erosion (e.g., titanium nitride applied by physical vapor deposition) or hot corrosion (e.g., platinum aluminides) performances, and (c) ion implantation and chemical surface treatments in conjunction with shot peening and soft coatings and lubricants to reduce fretting fatigue damage by means of a surface modification treatment (Ref 34)
- Reuse of components under a damage tolerance-based life cycle management scheme, achieved using five steps: (1) determination of stress and temperature data, (2) identification of the fracture critical location in the component of interest, (3) determination of the stress-intensity factor, (4) generation of fracture mechanics data for safe inspection interval calculations, and (5) generation of probability of detection (POD) curves from nondestructive inspection (NDI) data

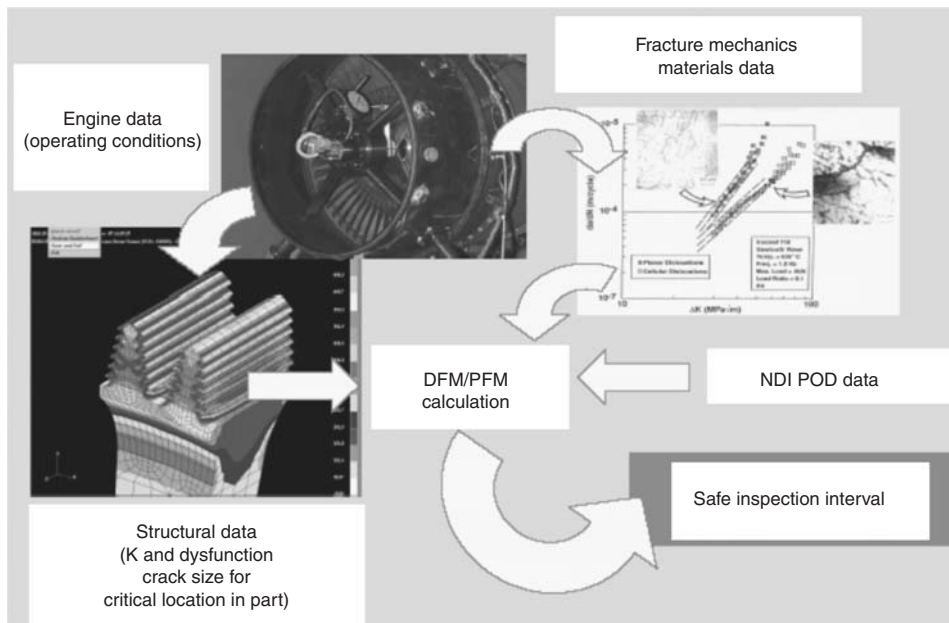

Fig. 15 Steps associated with safe inspection intervals (SII) calculation for damage tolerance based life management of critical engine parts

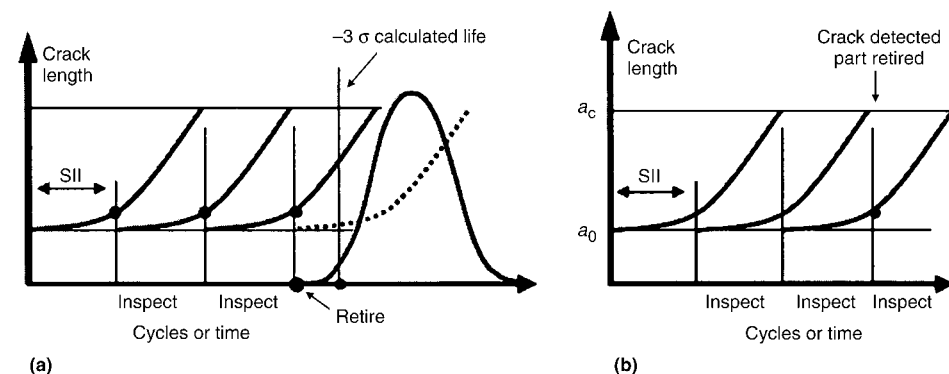

Fig. 16 Application of damage tolerance by ENSIP (a) and RCF (b) and relation to safe inspection interval (SII)

Prevention and Control

Control and prevention are both issues used to describe the procedures necessary to provide

effective corrosion maintenance on military systems. In effect, they must always be considered as complementary because they provide a synergistic effect when each achieves its specific action (Ref 35).

Corrosion control usually includes:

- Corrosion detection
- Corrosion removal
- Renewing the protective systems

On the other hand, corrosion prevention is mainly devoted to:

- Material design
- Surface treatments, finishes, and coatings
- Corrosion inhibitors, compounds, and sealants
- Preservation techniques

The entire process, including all these phases, has been recently called corrosion surveillance (Ref 36) and indicates the increasing interest from systems operators in this matter. This interest is largely due to the growing number of aged fleets that no longer respond to a simple "find and fix" maintenance approach. In addition, the attention to corrosion prevention and control has strongly increased in the past decade because of the very important role played by environmental constraints (Ref 37). In particular, corrosion prevention of aging systems is strongly dependent on the application of new water-displacement compounds and advanced coating and new plating alternatives. Previously successful chromic anodize and cadmium and chromium plating are being replaced with newer, safer materials.

Nevertheless, taking into account the strong interconnections existing between corrosion and other structural failures that can affect highly engineered systems, the monitoring of a much more complex number of parameters not always directly linked to corrosion has recently been introduced to preserve the safety and readiness of military systems (Ref 38).

Usage Monitoring (UM) Systems

Usage monitoring systems are increasingly introduced on aging military systems to guarantee an optimized aircraft management or to monitor the events that can lead to damage (excessive G forces, hard landings, etc.). The general trend in UM systems development is unambiguously directed toward integration in the avionic structure, in order to use the information provided by the interface progress unit (IPU), and consequently to have all the data immediately available for calculation. The Eurofighter is a case in point (Ref 39), whose UM system (Fig. 18) is subdivided into:

- Engine UM
- Structural UM
- Secondary power system UM
- Aircraft system UM

Health Monitoring (HM) Systems

The development of microelectronics has shown new ways to monitor structures and systems by means of sensors. As a matter of fact, their reduced dimensions and increased computer performance (that now offers the possibility of fast signal processing) make them currently available at a reasonable price for the monitoring of weight-optimized structures (Ref 40). In effect, an integrated HM system allows the implementation of an effective on-condition inspections program, the main benefits being:

- Avoidance of expensive conventional inspections for life extension in difficult-to-access areas of the aircraft

- Increase of time between inspections
- Increase of aircraft availability
- Increase of useful life without direct repair measures

An aircraft health monitoring system consists of sensors, signal amplifier, and filter and signal processing that, used in conjunction, enables the detection of a signal eventually related to structural damage.

Three types of sensors are most commonly suitable: fiber optic, piezoelectric, and sensory foils. The first, interesting for its low cost, low weight, low power demand, and long lifetime, has already proven to be particularly effective in damage identification by means of acoustic emission and is easily embedded into fiber composite materials.

Fig. 17 Typical residual and circumferential stress distributions around a cold expanded hole

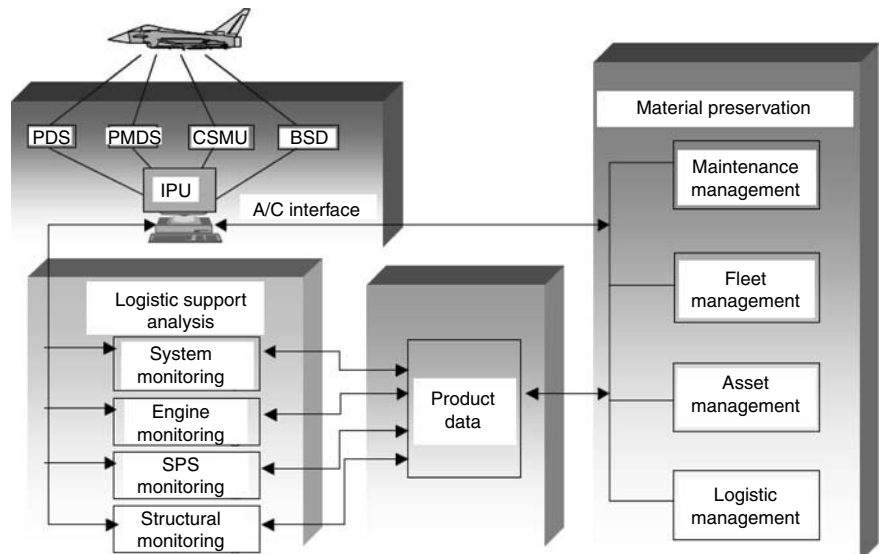

Fig. 18 Usage monitoring system data processing for the Eurofighter

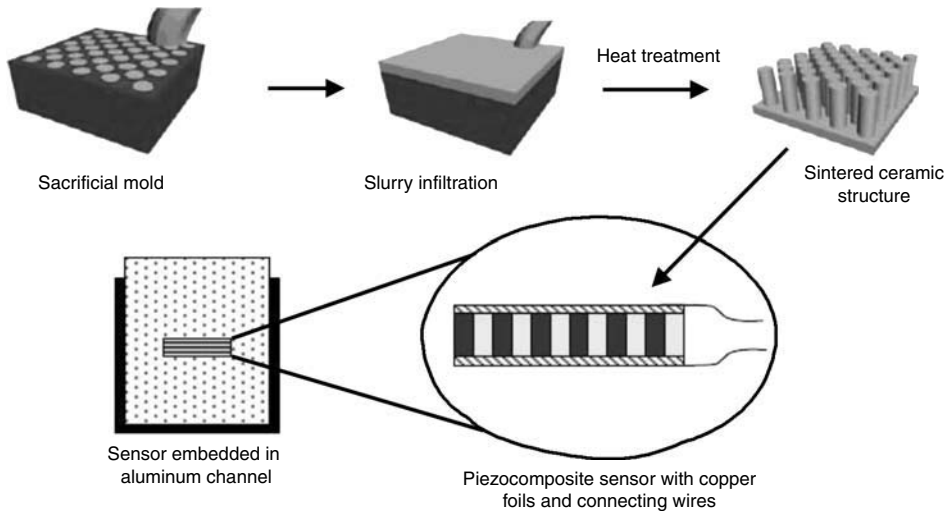

Fig. 19 Process for making the embedded piezoelectric ceramic-polymer composite sensors

Fig. 20 Thin-film bimetallic sensing element

Particularly interesting are the sensory foils, where piezoelectric sensors are embedded together with the wiring between two foils, bonded onto the structure, or embedded in a group structure as shown in Fig. 19 (Ref 41).

Wireless galvanic sensors (Ref 42–44) are a different class of sensors, specifically dedicated to the diagnostics of corrosion nucleation on aging aircraft (Fig. 20). In this case, an increase in the current circulating between the two electrodes embedded in the sensors is the early signal of an increase in corrosiveness of the local environment.

Prediction Techniques

Equivalent Pre-crack Size Approach. This is a risk-analysis approach based on the use of the probability of failure during a flight at different times throughout the life of the aircraft, where each structural location considered is assumed to have a single critical flaw whose size at a given time is grown from a probability distribution of equivalent initial flaw sizes (EIFS) or alternatively equivalent pre-crack sizes (EPS) until failure (Ref 45, 46). This approach is considered a very promising tool to predict fracture on aging structures where pitting corrosion plays an important role as a stress-concentration factor for future fatigue crack growth. By including all significant uncertainties, such as EPS on its own, possible load history, and material property variation, the risk of failure can be calculated (Ref 47).

The main uncertainties that govern the probability distribution at failure are usually due to the variability in:

- The EPS at the start of the fatigue life of the airframe
- Crack growth rates
- The fracture toughness of the material
- The maximum load in each flight
- The accuracy in calculating aircraft fatigue life consumed that relates to the amount of crack growth experienced based on the measured loading sequence

Life-Cycle Cost Modeling and Simulation.

An effective cost-estimating methodology to forecast costs associated with maintaining an aging aircraft usually combines the traditional operational and support cost elements with an expert analysis system. The result of this combination provides the capability to evaluate multiple and simultaneous “what if?” scenarios in order to weigh the effects of operational changes such as the number of aircraft, personnel to aircraft ratio, or annual flying hours.

To deal with the unavoidable uncertainty of long-term forecast estimates, analysts have to provide a range of estimated costs; this is generally accomplished by the use of probability distributions taking advantage of Monte Carlo techniques. The main strength of life-cycle cost modeling and simulation is its built-in flexibility. The model can be updated with the very latest information as it becomes available over time.

Holistic Life-Prediction Methodology (HLPm). This is in effect a proactive structural integrity methodology that looks at the design as a whole, where concepts of failure processes and pathology pervade all the phases of the design itself (Ref 48). Here, probability of occurrence of specific corrosion, wear, fretting, and thermal degradation, acting singly or conjointly with fatigue, are acknowledged as part of the failure process (Ref 49). This is achieved by means of a constant evaluation, model, and test method

development. Based on HLPm, the USAF has developed since the late 1990s the environmental and cyclic life interaction prediction software (ECLIPSE), which has been extensively exercised on lap-joint geometries and on early pitting-to-fracture components. The expected benefits from introduction of this program in conjunction with specific NDI activity on the aircraft maintenance life are currently under investigation.

Corrosion in Supercritical Water—Waste Destruction Environments

R.M. Latanision, Exponent
D.B. Mitton, University of North Dakota

THE PRACTICALITY of supercritical water oxidation (SCWO) technology for destroying hazardous materials was explored in the early 1980s. Capitalizing on the work of earlier research, the possibility of extraordinarily high destruction efficiencies was recognized. Diverse types of aqueous waste that incorporate relatively dilute (≈ 1 to 20%) quantities of organic components may successfully be treated by using this methodology. The two primary classes of waste that are being considered for destruction by SCWO are military and industrial wastes, including wastewater sludge. Military waste tends to present a severe challenge with respect to corrosion and solids handling, while the latter class is relatively innocuous (Ref 1).

Virtually any pumpable fluid may be treated by SCWO. These wastes (and the interested organizations) may include: human metabolic byproducts that could potentially be produced during long-term space flight (National Aeronautics and Space Administration, NASA); regulated wastes (U.S. Environmental Protection Agency, EPA); mixed low-level radioactive waste (U.S. Department of Energy, DoE); and explosives or nerve and blister agents destined for chemical demilitarization (U.S. Department of Defense, DoD). The DoD has a substantial quantity of both stockpiled waste (characterized and stored in a controlled environment) and nonstockpiled waste (all chemical agent materials outside the stockpile) that need to be destroyed. By exploiting the properties of water above its critical point, 374 °C (705 °F) and 22.4 MPa (221 atm) for pure water, this technology is capable of providing rapid and complete oxidation of the organic component, with high destruction efficiencies. The relatively low viscosity of supercritical water promotes mass transfer and mixing, while the low dielectric constant promotes dissolution of nonpolar organic materials. In conjunction with the high temperatures (which increase thermal reaction rates), these properties provide a medium in which mixing is fast, organic materials dissolve well and react quickly with oxygen, and salts precipitate (Ref 2). While the products of

hydrocarbon oxidation are CO₂ and H₂O, heteroatoms are converted to inorganic compounds (usually acids, salts, or oxides in high-oxidation states). The formation of acids at elevated temperatures and pressures under very oxidizing conditions may result in severe corrosion. Thus, while SCWO is an effective process for the destruction of such waste, degradation of the materials of fabrication is a serious concern. The potential for identifying a universal construction material capable of maintaining system integrity when exposed to the highly aggressive conditions associated with the various sections in the SCWO process stream is extremely unlikely. Ultimately, the practicality of SCWO may be limited by the ability to control corrosion (Ref 3–5).

The Unique Properties of Supercritical Water

As presented in Fig. 1 (Ref 6), the properties of water undergo major changes in the vicinity of the critical point. In this regime, the viscosity (Fig. 1a) decreases with increasing temperature, and the density (Fig. 1b) is intermediate between that of liquid water (1.0 g/cm³) and low-pressure water vapor (<0.001 g/cm³). At SCWO conditions, water density is typically 0.1 g/cm³, and consequently, the properties of supercritical water are significantly different from liquid water at ambient conditions. The dielectric constant (Fig. 1c) reflects the ability of water to support ionic reactions. At a pressure of 25 MPa (250 bar), the dielectric constant drops from approximately 80 at room temperature to 2 at 450 °C (840 °F), and the ionic dissociation constant (Fig. 1d) decreases from 10⁻¹⁴ at room temperature to 10⁻²³ at supercritical conditions. These changes result in supercritical water acting essentially as a nonpolar dense gas with solvation properties approaching those of a low-polarity organic. Inorganic solubility is significantly decreased, and a concurrent increase in the solubility of organics and miscibility of many

gases is seen (Ref 7). The solubility of NaCl, for example, decreases from approximately 37 wt% at 25 °C (75 °F) to only 120 ppm at 550 °C (1020 °F), while the solubility of organics and gases increases substantially above the critical point. With these solvation characteristics, when organic compounds and oxygen are dissolved in water above the critical point, kinetics are fast and the oxidation reaction proceeds rapidly to completion, with times required for complete reaction ranging from a few seconds to a few minutes for most wastes (Ref 2). At typical operating conditions (25 MPa, or 250 bar; 600 °C, or 1110 °F), destruction and removal efficiencies (DRE) can exceed 99.999%, with residence times on the order of a minute or less (Ref 8). For instance, the DRE recorded during kinetics studies of a number of chemical nerve agents, GB (sarin), VX, and mustard gas, have been shown to be on the order of 99.9999% or higher (Ref 9).

The Economics and Benefits of SCWO

The main technological advantages of SCWO include:

- System is entirely self-contained and can be shut down quickly
- High destruction efficiencies with low reactor residence times
- Relatively low operating temperature precludes the formation of nitrogen oxides
- Ability to capture the reaction products for analysis, storage, or further treatment
- Potential for a compact portable system that can be moved to the toxic waste site (Ref 2), thus circumventing public opposition to the transportation of hazardous waste

Supercritical water oxidation is a promising technology applicable to many dilute aqueous organic wastes (Ref 7, 10, 11) with total organic carbon content in the range of 1 to 20 wt%. As a result of the relatively low operating

temperature, NO_x and SO_2 compounds are not produced (Ref 7). The latter may be particularly important during the destruction of explosives that produce nitrogen oxides during incineration (Ref 12). From the perspective of both economics and safety, the high pressure requirements of this technology are a potential expense. SCWO must still be able to demonstrate both economical competitiveness and system endurance. While this has been accomplished for benign wastes, this methodology is still comparatively expensive for aggressive feeds and currently does not appear to be competitive for private sector applications (Ref 1).

Facility Design Options

Current supercritical toxic waste systems typically incorporate either a downflow or

tubular reactor configuration. Because it provides the lowest capital cost, a tubular reactor is preferred for relatively innocuous SCWO feeds. Conversely, a lined vessel is the preferred reactor configuration for aggressive feeds. The liner isolates the processing environment from the pressure boundary (Ref 1). Figure 2 presents a schematic diagram of a downflow vertical vessel waste treatment system based on SCWO technology (Ref 13). In this process, aqueous organic waste (1), which may be neutralized with a caustic solution (2) or have fuel (3) injected for startup, is initially pressurized from ambient to the pressure of the reaction vessel and pumped through a heat exchanger (4). This helps to bring the stream up to the desired temperature before reaching the reactor. At the head of the reactor (5), the stream is mixed with air or oxygen. In some cases, an oxidant such as hydrogen peroxide (H_2O_2), which catalytically decomposes to

oxygen and water, may be used in preference to either air or oxygen; however, this is not economically advantageous. The reaction occurs in the top zone (6), where spontaneous oxidation of the organics liberates heat and raises the temperature to levels as high as 650°C (1200°F). Organic destruction occurs quickly, with typical reactor residence times of 1 min or less. As a result of their low solubility, salts precipitate and impinge on the lower zone (7), which is maintained at a temperature of approximately 200°C (390°F) by injecting water. The salts may be continuously taken off as a brine (8) or removed periodically as solids. The primary effluent (9) passes out of the top of the reactor into a separator (10), where the gas (11) and liquid (12) are quenched and separated; however, a portion of the liquid may be recycled (13).

The downflow and tubular reactor designs are by no means exclusive, and over the years, a number of alternative reactor arrangements have emerged. Design modifications typically attempt to limit the concerns associated with corrosion or plugging. As previously indicated, in its simplest form, a corrosion-resistant liner may be incorporated; however, more complex designs have included the dual-shell pressure-balanced vessel (Ref 14), a coaxial hydrothermal burner (Ref 15), and the transpiring wall reactor. In the transpiring wall reactor (Fig. 3), an attempt is made to reduce or prevent corrosion of the pressure-bearing wall and plugging of the reaction vessel through a reactor design modification (Ref 16). The latter incorporates an internal rinsing flow pattern (in the inward radial direction) superimposed on the main axial flow. The transpiring water forms a lower-temperature fluid boundary that prevents direct contact of the hot corrosive media with the pressure-bearing wall, thus reducing the potential for degradation. In addition, it is assumed that salts will not build up on the inner wall if the salt particulates cannot reach the wall or, alternatively, if they redissolve (as a result of the lower fluid temperature) prior to reaching the wall. The multiple inlets at the top of the reactor presented in Fig. 3 permit water and fuel (1), wastewater (2), and oxygen (3) to be added and mixed. The reactor has numerous side inlets (4) for the transpiring water (5). The annular channel between the inner wall of the vessel and the porous metal insert (6) can be divided into several chambers to permit independent control of the transpiring fluid flow rate.

In many industrial applications, increased throughput is frequently accomplished by means of scaleup; however, in the case of SCWO, it may be preferable to achieve this by running parallel systems (Ref 2).

Materials Challenges

For many waste streams, corrosion continues to be one of the central challenges to the full development of this technology. The system

Table 1 Forms of corrosion for selected construction materials and environments

Material	Environment	Temperature		Form of Corrosion	Reference
		°C	°F		
Iron-base alloys					
316	Deionized water	300–500	570–930	Uniform	17
	Deionized water	≈ 374	≈ 705	Some pitting	18
	Highly chlorinated organic	600	1110	Wastage, stress-corrosion cracking (SCC)	19
	pH higher than 12	500	930	SCC and other forms	17
Nickel-base alloys					
Alloys 625 and C276	Deionized water	300–500	570–930	Uniform and pitting	17
	Highly chlorinated organic	600	1110	Wastage	19
Alloys 625 and 718	Low-acid chloride and sulfate (with solid deposits)	600	1110	Pitting and crevice corrosion	20
Alloy 625	Methylene chloride, isopropyl alcohol, NaOH	580	1075	SCC and pitting	3
C276	Methylene chloride, isopropyl alcohol, NaOH	380	715	SCC and pitting	3
G30	CH ₂ Cl ₂ plus H ₂ O ₂	420	790	Acceptable corrosion behavior	21
	Highly chlorinated organic	600	1110	Moderate corrosion behavior	22
Titanium					
Grade 7	0–10 pH + Cl, NO ₃ , SO ₄ , PO ₄ (a)	500	930	Uniform	17
Grade 12	Low-acid chloride and sulfate (with solid deposits)	600	1110	Minor oxide spallation	20
Grade 2	Low-acid chloride and sulfate (with solid deposits)	600	1110	Pitting	20
Noble metals					
Pt, Pt-10Ir, Pt-30Rh	Low-acid chloride and sulfate (with solid deposits)	600	1110	No evident attack	20
Pt	Mustard simulant (HCl and H ₂ SO ₄)	350	660	Serious attack	9
	Mustard simulant (HCl and H ₂ SO ₄)	450 or 550	840 or 1020	Much more resistant to attack than at 350 (660)	9
Ceramics					
Alumina, SiC, Si ₃ N ₄ , zirconia	2–12 pH, 400 ppm Cl	350–550	660–1020	Uniform and other forms	17
Alumina, SiC, Si ₃ N ₄ , zirconia, sapphire	HCl plus H ₂ O ₂	465	870	Generally low resistance to degradation	23

(a) Acids measurable as wt%

must accommodate an aggressive oxidizing environment over a wide temperature range at high pressure, with no loss of containment resulting from a corrosion-related breach of the

pressure-bearing wall. A summary of selected materials exposed to various environments as well as the observed form of corrosion is presented in Table 1.

Figure 4 presents the potential-pH (Pourbaix) diagram for iron at a pressure of 50 MPa (500 bar) and 400 °C (750 °F). The lines representing the thermodynamic equilibrium for the

various species are labeled. The two hatched regions indicate the range of potential and pH conditions within which SCWO systems, represented by the hatched rectangle, and supercritical thermal power plants (SCTPP), represented by the hatched oval, are likely to operate. In relation to both pH and oxidizing potential, it is clear that the conditions associated with SCWO are substantially more aggressive than those for SCTPP. Further, because the majority of SCWO systems are designed to operate with high partial pressure of oxygen, p_{O_2} , the upper region of the hatched rectangle best reflects SCWO conditions. On the other hand, SCTPP generally operate with low levels of oxygen, possibly even employing reducing agents such as hydrazine or ammonia, and it is estimated that the potential would be in the lower half of the oval representing these systems (Ref 24). Background on potential-pH diagrams can be found in the article "potential versus pH (Pourbaix) Diagrams" in *ASM Handbook*, Volume 13A, 2003.

Although they have been included as a base material in many research programs, stainless steels such as 316L are not likely to be used for fabrication of SCWO systems designed for aggressive waste streams. Generally, they exhibit unacceptable performance (Ref 5, 17, 18, 25), a susceptibility to stress-corrosion cracking (SCC) in acidic environments (Ref 19, 26), pitting and crevice corrosion in sludge (Ref 5), wastage on the order of 50 mm/yr (2000 mils/yr) (Ref 19), and SCC in highly chlorinated environments (Ref 19). Figure 5 presents a micrograph of a cracked section at the top of a 316L alloy U-bend sample exposed to a highly chlorinated oxidizing

environment for approximately 66 h at 600 °C (1110 °F) (Ref 27). Nevertheless, binary iron-base alloys containing very high levels of chromium ($\approx 50\%$) may show some promise (Ref 28); however, additional testing is still required.

Conversely, as a result of a superior severe service history, high-nickel alloys have been selected for fabrication of many of the existing benchscale and pilot plant reactors. However, they are not without problems and, when exposed to aggressive conditions, may suffer significant degradation including, but not limited to, wastage on the order of 18.8 to 19.0 mm/yr (740 to 750 mils/yr), pitting, SCC, and dealloying (Ref 3, 9, 17–19, 22, 25, 29–36). Dealloying is seen in the cross section of a C276 alloy tube that was exposed to an aggressive chlorinated environment at a temperature estimated to be high but below the critical point (Fig. 6). While the macroscopic dimensions of the tube have not changed, the dealloyed layer has lost essentially all of the nickel component and is friable (Ref 31).

There is evidence for a correlation between chromium content and corrosion resistance for nickel alloys in SCWO systems (Ref 37), and certainly, the high-chromium alloys such as G30 ($\approx 30\%$ Cr) generally exhibit reasonable corrosion resistance (Ref 5, 21, 38). In the case of binary nickel-chromium alloys exposed to oxidizing chlorinated supercritical conditions (500 °C, or 930 °F), research suggests that chromium levels above approximately 20% may actually be deleterious to corrosion behavior (Ref 39). This observation has recently been

corroborated by additional research that also reveals the counterproductive nature of a high chromium content for binary nickel-chromium alloys with as much as 45% Cr (Ref 40). In this case, the authors observed a corrosion minimum in the region of 25% Cr. Ultimately, however, this trend may not be valid for multi-element alloys.

There is a body of literature indicating that the experimentally observed degradation can be more pronounced in the high-subcritical regime (Ref 30–33, 41) and that the aggressiveness of the solution may actually decrease above the critical point (Ref 42). This has even been noted in the case of SCC, which tends to be less probable at supercritical temperatures (Ref 20, 33).

A phenomenological approach has been adopted to explain the decrease in corrosion in the near-critical region (Ref 43). This treatment

Fig. 4 Potential-pH diagram for iron in supercritical aqueous solution at 400 °C (750 °F) and 50 MPa (500 bar), showing the approximate regions in potential-pH space for the operation of supercritical water oxidation (SCWO) reactors and supercritical thermal power plants. Source: Adapted from Ref 24

of the subject considers H^+ and O_2 as the only aggressive species, and Cl^- -induced localized attack is not considered. By calculating the relative corrosion rate (R/R^0), based on changes in the hydrogen ion concentration and the density of water as a function of temperature over the temperature range associated with SCWO systems, an increase with increasing temperature is observed until a maximum is reached as the critical point is approached (Fig. 7). With a further increase in temperature, the relative corrosion rate decreases. This decrease is associated with a rapid reduction in the concentration of aggressive species as a function of an increasing supercritical temperature. The reduction in aggressive species reflects the combined effect of a decrease in the dissociation constant (resulting in a decrease in acid dissociation) and a decrease in the solution density.

It is essential, however, to consider other contributory factors not strictly related to changes in the solution. Experimental observations suggest that both time and system pressure influence the corrosion phenomena. For example, the upper temperature limit for severe corrosion depends on the pressure and thus the density of the solution, with higher densities favoring corrosion (Ref 41). Further, even at supercritical conditions, a substantial increase in corrosion may be observed after extended exposure times (for example, alloys 625 and 718 in Ref 20). Finally, while SCC appears to be more probable at subcritical temperatures (Ref 20, 33), SCC of alloy 625 has been reported for complex feeds at supercritical temperatures (580 °C, or 1075 °F) after extended exposure, on the order of 300 h (Ref 3).

There is an apparent dichotomy in the corrosion resistance data for titanium. Preliminary results indicated acceptable resistance to chlorinated, but not to nonchlorinated, acidic chemical

agent simulant feeds (Ref 9). Outstanding performance of titanium has been reported at subcritical temperatures, while performance at supercritical temperatures is comparable to the nickel alloys (Ref 20); thus, titanium is viewed as a potential liner material (Ref 20, 44). Nevertheless, through-wall pitting of liners during destruction efficiency testing of a chlorinated waste has been reported (Ref 45). At elevated temperatures, potential problems with creep need to be considered for this material. In addition, the pyrophoric nature of titanium has caused some problems (Ref 1).

While incorporating noble metals or their alloys in the fabrication of SCWO systems would significantly increase cost, this may be one potential solution to severe corrosion problems for highly aggressive military waste streams. Although the corrosion resistance of platinum may be good at supercritical temperatures (Ref 20), in acidic chlorinated feeds it can suffer high rates of degradation at subcritical temperatures (Ref 9). Even in the low supercritical temperature range, corrosion rates can be higher than desirable (Ref 20). For systems incorporating a platinum liner, this would necessitate a potentially troublesome transition between platinum (supercritical temperature region) and a second material (subcritical temperature region). The potential for erosion or erosion-corrosion could be exacerbated in SCWO systems by entrained solids such as salts, oxides, and corrosion products (Ref 8). Erosion problems were recently encountered during testing of a platinum liner exposed to a VX hydrolysate feed, confirming the need to consider not only the potential for corrosion but also for flow-related phenomena in these systems (Ref 1).

The problems associated with the corrosion of various alloys has prompted research into ceramic materials; however, ceramics have generally exhibited less than satisfactory resistance (Ref 9, 46). Degradation was found to proceed predominantly either by homogeneous surface attack or by grain-boundary diffusion (Ref 23). In addition to the effect of system conditions such as temperature and feed stream composition, at least in the case of alumina, degradation also depends on the purity, porosity, and microstructure of the ceramic (Ref 46).

Fig. 7 The relative corrosion rate (R/R^0) at two different molal concentrations of HCl (m_{HCl}^0) for the temperature range associated with supercritical water oxidation systems at a pressure of 50 MPa (500 bar) and activation energies (E) of 25, 50, and 100 kJ/mol. Source: Adapted from Ref 43

and may consist of a removable or replaceable solid-wall corrosion-resistant barrier. The aspect ratio of the reactor must be suitable for practical mechanical incorporation of the liner (Ref 1). Currently, no universal liner material has been identified that will meet the requirements of all SCWO feeds; thus, liners must be selected to accommodate the character of individual feed streams. Titanium and platinum are the liner materials most frequently suggested for solid-wall liners; however, as previously indicated, they have limitations.

A transpiring wall can also be viewed as a type of liner, and this design has successfully been employed without corrosion of the transpiring wall platelets (fabricated from alloy 600) for several hundred hours of operation on chemical demilitarization feeds. Longer-term operational history is still desirable to confirm this trend (Ref 1).

Although feed neutralization (with NaOH, for example) has seen some success in SCWO systems for acidic feeds, it has been carried out without a full understanding of its effect on corrosion. Typically, feed neutralization involves stoichiometric quantities of neutralizer; however, there is evidence to suggest that the most favorable thermodynamics are obtainable by adjusting the feed stream chemistry (Ref 31). This would, however, necessitate the use of in situ monitoring. An additional disadvantage of neutralization is the production of salt species that can lead to plugging of the system. To some extent, for wastes that do not already contain salts, this can be circumvented by restricting neutralization to the cool-down section of the system (Ref 48). In this way, salts that would normally be formed in the supercritical regime do not deposit on the reactor walls. This modification has been adopted in Europe by Chematur Engineering (Ref 1).

Ultimately, to reduce degradation to an acceptable level in the various regions of SCWO systems handling aggressive influents, it may be necessary to adopt a synergistic approach incorporating feed chemistry control, reactor design modifications, and intelligent materials selection.

The Future

There is little doubt that this promising technology has both economic and environmental incentives; nevertheless, the corrosion of the materials of fabrication persists as a serious concern, and substantial research is needed to identify materials or methods to reduce degradation to an acceptable level. Some key areas for future research could include:

- Evaluate the effect of entrained solids on the endurance and life of construction or liner materials
- Develop an in-depth understanding of the relationship between solid deposits (salts, for example) and the corrosion rate and mode

Mitigation of System Degradation

While corrosion continues to be a challenge, a number of control approaches have been adopted. Feed stream dilution could reduce the severity of corrosion, but the required dilution may be so large as to make this procedure economically unattractive (Ref 47).

Because it provides the lowest capital cost, a tubular reactor design is favored for relatively innocuous SCWO feeds. Alternatively, for more aggressive feeds, a lined vessel is the preferred reactor configuration. The liner isolates the processing environment from the pressure boundary

- Assess innovative reactor designs that may provide potential solutions to materials degradation challenges
- Design and fabricate robust in situ potential, pH, and corrosion-monitoring electrodes
- Investigate the link between degradation and (i) the elemental alloy composition, (ii) various temperature zones, (iii) system pressure, and (iv) influent composition

With respect to material performance, feed chemistry control can provide a less challenging environment and Pourbaix diagrams can be used to guide adjustments for this purpose. There is however, a lack of data for these diagrams at higher operating temperatures. For the longer term, and in parallel with experimental efforts, development of appropriate instrumentation techniques and data collection for the generation of Pourbaix diagrams for materials of construction at higher temperatures is desirable.

ACKNOWLEDGMENT

The work reported in this article was performed while the authors were affiliated with The H.H. Uhlig Corrosion Laboratory at the Massachusetts Institute of Technology.

Corrosion in Supercritical Water— Ultrasupercritical Environments for Power Production

Gordon R. Holcomb, National Energy Technology Laboratory

THE OPERATING TEMPERATURES AND PRESSURES of steam boilers and turbines have been increased to improve efficiencies in steam and power production. Improvements in materials properties, such as high-temperature strength, creep resistance, and oxidation resistance, have enabled this increase. From 1910 to 1960, there was an average increase in steam temperature of 10 °C per year, with a corresponding increase in plant thermal efficiency from less than 10 to 40% (Ref 1).

While there is no specific definition of ultra supercritical (USC), plants operating above 24 MPa (3.5 ksi) and 593 °C are currently deemed as such (Ref 2). As the state of the art advances, the conditions regarded as USC will probably increase. Plants operating below 24 MPa are subcritical, and those at or above 24 MPa are supercritical (SC) (Ref 2). The critical point of water is 22.1 MPa (3.2 ksi) not 24 MPa—the 24 MPa distinction is based more on the lack of an evaporation step in the steam cycle. Subcritical plants may, at some point in their steam cycle, have supercritical steam.

The first commercial boiler with a steam pressure above its critical value of 22.1 MPa (3.2 ksi) was the 125 MW Babcock & Wilcox universal pressure (UP) steam generator in 1957 at the Ohio Power Company's Philo 6 plant (Ref 3). A UP boiler can operate at both subcritical and supercritical conditions. It delivered steam at 34.1 MPa (5.0 ksi) and 621 °C, with two reheats of 566 and 538 °C. The pressure and temperatures of the primary, first reheat (if present), and second reheat (if present) are designated by a nomenclature such as 34.1 MPa/621 °C/566 °C/538 °C for the Philo 6 plant. In 1960, Eddystone 1 reached a world record in efficiency of 40%, operating at 34.5 MPa/649 °C/565 °C/565 °C (Ref 1, 2). The Eddystone 1 plant, and others of its generation, soon reduced operating temperatures and pressures primarily because of thermal fatigue issues

within the boiler (Ref 1). Eddystone 1 continues to operate at 32.4 MPa/610 °C (Ref 2). It still uses the highest steam pressures and temperatures in the world. Since 1960, the overall trend of increasing temperatures and pressures has stopped and stabilized at approximately 538 °C and 24.1 MPa (3.5 ksi) for U.S. power plants (Ref 2).

Since the 1970s, advances in the high-temperature strength of ferritic steels have allowed increases of operating temperatures and pressures without the thermal fatigue issues of the austenitic steels that had to be used to obtain the required high-temperature strengths in the early 1960s. The term *ferritic steels*, as used here, refers to the equilibrium structure. In practice, a martensitic or partially martensitic structure is obtained from heat treating. Currently, the most efficient fossil power plants operate at 24 MPa/600 °C and are deemed state of the art. Operations at 28 MPa/630 °C are expected in the near term (Ref 2). Current research programs are aimed at increasing the operating conditions to as high as 760 °C and 37.9 MPa (5.5 ksi).

Water Properties

Several physical properties of water undergo large changes at or near its critical point (374 °C and 22.1 MPa, or 3.2 ksi) (Ref 4). Above 374 °C (705 °F), water vapor can no longer be compressed into a liquid. Density and dielectric constant decrease with increasing temperature and fall sharply at the critical temperature. The ionic product reaches a maximum at approximately 300 °C and also falls sharply at the critical temperature. Supercritical water is a low-density fluid that is a non-polar solvent with high solubilities for organic compounds and gases and low solubilities for salts.

Steam Cycle

A simplified water path in a large supercritical utility boiler, with a single reheat, is illustrated in Fig. 1. Input water from the boiler feed pump is preheated in the economizer and then travels up the water walls and into the separator. Steam from the separator is fed into the primary and secondary superheaters. From there, the steam goes to the high-pressure turbine, then to the reheater, the intermediate-pressure turbine, the low-pressure turbine, and then to the condenser. From the condenser, water goes back to the boiler feed pump to then repeat the cycle. One possible physical layout and position of the components within a supercritical boiler is shown in Fig. 2 (Ref 5).

Supercritical boilers are typically once-through systems but with the capacity to separate water from steam in the separator (particularly during startup). Boilers that operate at constant pressure in either subcritical or supercritical temperatures are UP boilers. Benson boilers operate in both subcritical and supercritical conditions but with a sliding pressure capability.

The Rankine cycle, in terms of temperature and entropy, is shown in Fig. 3 for a subcritical system and in Fig. 4 for a SC system. In these figures, the critical temperature is at the maximum in the saturated-liquid and -vapor curves. Under the saturated lines is a wet mixture; to the left of the saturated-liquid line is compressed liquid, and to the right of the saturated-vapor line is superheated vapor. In Fig. 3, liquid water is compressed from points A to B. The temperature rise (A-B) is exaggerated in Fig. 3 and is typically on the order of 0.6 °C. The heating that takes place from points B to C occurs first in the economizer, then in the water walls (the constant temperature evaporation step), and then in the superheater. Expansion takes place within the turbines from points C to D. Lastly,

unavailable heat is rejected to the atmosphere from points D to A. The SC cycle in Fig. 4 is similar (points B to E) but does not include the evaporation step, and so, energy is not needed to overcome the latent heat of evaporation. Also shown in Fig. 4 is a reheat step through points F to G. The unavailable heat is the area under the D-A step in Fig. 3 and the area under the H-A step in Fig. 4.

The thermal efficiency in converting heat into work in reversible Rankine cycles is the ratio of temperature-entropy area within the cycle to the combined areas of the cycle and unavailable heat. Supercritical systems allow the upper temperature to increase, which increases the cycle area and thus the thermal efficiency. Figure 4 shows how reheating also increases the thermal efficiency by raising the average maximum temperature.

The overall efficiency power generation station is the ratio of energy output to energy input and is a function of many factors: the thermal efficiency, the quality of coal, the condenser pressure, and the heating value (heat of reaction) used. Differing methods for calculating the heating value of fuel result in European plant efficiencies being cited as 3 to 5% higher than comparable plants in the United States.

An additional point is the distinction between a 1% increase in efficiency and a percentage improvement in efficiency. The first is absolute, and the second is relative. So, with a base efficiency of 37%, a 1% increase in efficiency corresponds to a 2.7% improvement (relative increase). For more information, see the subsequent section on efficiency.

Steam Cycle Chemistry

The control of water chemistry in the steam cycle of a power plant is important for corrosion control, deposition prevention, and higher cycle efficiency (Ref 6). There are three basic steps in controlling the water chemistry: removal of impurities (in makeup water, feedwater, and condensate), control of feedwater pH, and boiler water treatments (for once-through systems, these are feedwater treatments).

Impurity removal is by boiler blowdown, mechanical deaeration in the condenser and deaerator, and oxygen scavenging (usually with hydrazine) (Ref 6). For once-through systems, demineralization (condensate polishing) is also performed.

Feedwater pH is normally controlled by injection of ammonia or amines to maintain feedwater pH between 9.2 and 9.6, as measured at room temperature (8.8 to 9.2 when copper alloys are also present in the feedwater system) (Ref 6). These high pH values help protect carbon steel components at low temperatures. Ammonia and amines are weak bases, so they have little effect in raising the pH at high temperatures. In the absence of strong bases, such as phosphate or hydroxide, the pH at elevated temperatures is close to neutral.

In subcritical boilers, a variety of boiler water treatments (usually containing phosphates or hydroxides) is used that is not used in higher-pressure systems. For higher-pressure once-through systems, either an all-volatile treatment (AVT) or an oxygenated treatment (OT) is used

(Ref 6). In the AVT, the pH is controlled as described previously, with ammonia or volatile amines. There are no phosphates or buffering salts, so there is little tolerance for contamination, and thus condensate polishers are required. The AVT was first used in supercritical boilers.

Oxygenated treatment (Ref 6) is relatively new in the United States but has been used elsewhere for many years. Ultrapure feedwater is required ($<0.15 \mu\text{S/cm}$ cation conductivity). Oxygen, either in the form of O_2 gas or hydrogen peroxide, is added to the feedwater at a controlled rate. The oxygen promotes the formation of a dense and protective iron-oxide film on the boiler and feedwater piping. Condensate polishers are required in OT programs. Oxygenated treatment can be used alone, termed neutral water treatment, with oxygen controlled to ~ 200 ppb, or in combination with ammonia, termed combined water treatment, with oxygen controlled between 50 to 200 ppb and with ~ 200 ppb ammonia.

Materials Requirements

The components exposed to supercritical water in SC and USC power plants include high-pressure steam piping and headers, superheater and reheater tubing, and water wall tubing in the boiler, and high- and intermediate-pressure rotors, rotating blades, and bolts in the turbine section (Ref 7). A synopsis of the materials requirements for each of these is presented as follows.

Steam piping and headers require high-temperature creep strength. These are heavy-section components and are particularly subject to fatigue from thermal stresses. Ferritic steels have lower thermal expansion coefficients than austenitic steels and so are preferred with respect to thermal fatigue. Current ferritic steels are limited to 620°C , while the theoretical limit is thought to be approximately 650°C (Ref 7).

Superheater and reheater tubing requires high-temperature creep strength, thermal fatigue strength, weldability, fireside corrosion resistance, and steamside corrosion resistance. Ferritic steels are preferred due to their thermal fatigue resistance. However, high-temperature creep strength currently limits these alloys to 620°C (650°C theoretical limit). Fireside corrosion resistance further limits ferritic steels to approximately 593°C which corresponds to a steam temperature of approximately 565°C (Ref 7).

Waterwall tubing faces similar issues as superheater and reheater tubing but at lower temperatures, so that lower-alloyed materials are typically used.

High-pressure and intermediate-pressure rotors are large forgings that carry the rotating blades and transmit the mechanical energy. They are subject to centrifugal loads during operation and to thermal stresses during startups and

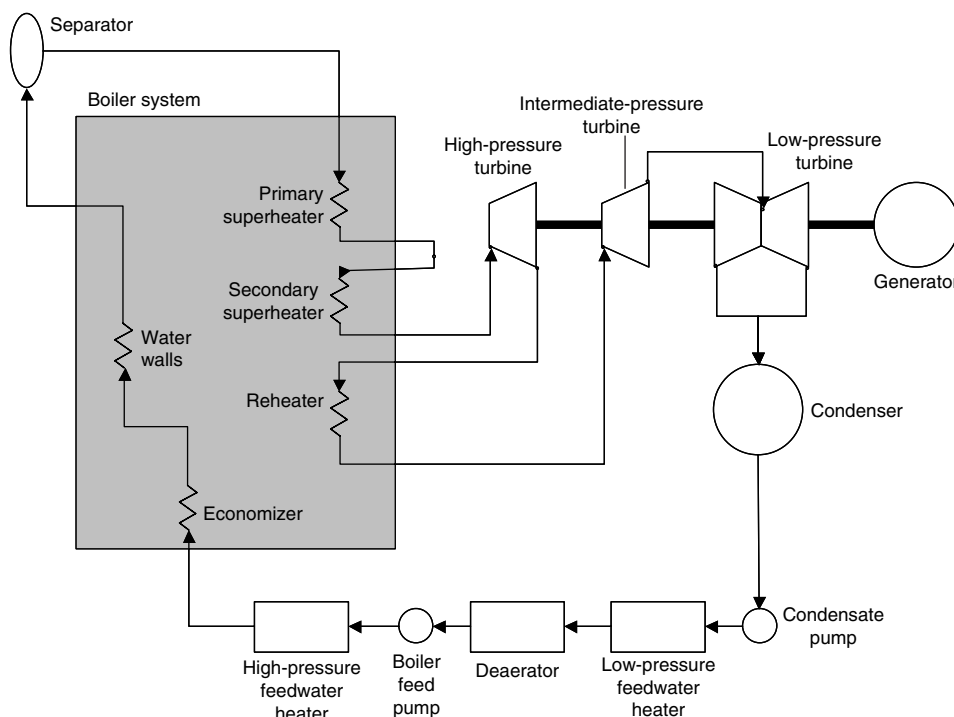

Fig. 1 Simplified water path in a large supercritical utility boiler, with a single reheat step

shutdowns. The key materials properties are creep strength, low-cycle fatigue strength, and fracture toughness (Ref 7).

Rotating blades require high-temperature strength, creep resistance, and a coefficient of thermal expansion similar to the rotor (Ref 7). In

addition, the alloys must be able to be peened. In each row of blades, a circular cover is used to couple the blades together and to act as a seal. The tenon part of the blades protrudes from the cover and is peened into heads, which attach the blades to the cover (Ref 7).

Bolts require high-temperature strength, creep resistance, notch sensitivity resistance, and a coefficient of thermal expansion similar to the rotor. The bolts must remain tight between scheduled shutdowns (20,000 to 50,000 h) (Ref 7).

Boiler Alloys

The alloys used (or proposed to be used) in SC and USC boilers can be broadly classified as ferritic steels, austenitic steels, and nickel-base alloys. Ferritic steels are currently limited to temperatures below 620 °C, with a theoretical limit of approximately 650 °C; austenitic steels are thought to have applications from 620 to 675 °C, and nickel alloys are used above 675 °C (Ref 2). Table 1 lists candidate alloys for USC boilers and their preferred applications (Ref 8, 9).

Ferritic boiler steels developed over the past 40 years are based on simple 2Cr, 9Cr, and 12Cr steels. Figure 5 shows the evolution of these steels, grouped into four generations by 10⁵ h

creep-rupture strength at 600 °C (Ref 7, 10). The first generation was developed in the 1960s by additions of molybdenum, niobium, or vanadium and has a maximum metal use temperature of approximately 565 °C (Ref 7). Metal temperatures are typically at least 28 °C (50 °F) higher than steam temperatures for tubing. They are roughly the same for headers and piping. The alloy HCM9M has had extensive use in superheater and reheater tubes, replacing 18Cr-8Ni steels for reheater applications (Ref 10). The alloy HT91 has been used extensively in Europe for tubing, headers, and piping. Poor weldability has limited its use in the United States and Japan (Ref 10). The second generation was developed between 1970 and 1985 by optimization of carbon, niobium, and vanadium and has a maximum metal use temperature of approximately 593 °C (Ref 7). The alloy ASME T91 has been used extensively for heavy-section components such as steam pipes and headers (Ref 10). The third

generation was developed between 1985 and 1995 by partially substituting tungsten for molybdenum and has a maximum metal use temperature of approximately 620 °C (Ref 7). The fourth generation is emerging by adding cobalt and increasing tungsten and is thought to have a maximum metal use temperature of approximately 650 °C (Ref 7).

The role of alloy additions is primarily to improve creep strength. Additions of tungsten, molybdenum, and cobalt are useful as solid-solution strengtheners. Some of the solid-solution strengthening from tungsten may be reduced by the formation of Laves phases (Ref 11). Additions of vanadium and niobium are useful as precipitation strengtheners and form fine carbide and nitride precipitates. Additional chromium provides solid-solution strength as well as corrosion resistance. The addition of nickel improves toughness at the expense of creep strength, which can be partially overcome by

replacing nickel with copper (Ref 7). The overall creep strength with time is shown schematically in Fig. 6, which shows how the creep strength decreases with time from various strengthening mechanisms (Ref 11). The nominal compositions of ferritic boiler steels are given in Table 2.

Austenitic steels evolved as shown in Fig. 7, beginning from alloys 302 and 800H (Ref 7, 10). Austenitic steels have better oxidation and fireside corrosion resistance than ferritic steels and thus are primarily candidates for the finishing stages in superheater and reheater tubing (Ref 7).

Alloying additions of titanium and niobium were added to stabilize the steels for corrosion resistance. Later, titanium and niobium were reduced (understabilized) to promote creep strength. Additions of copper are for precipitation strengthening, and tungsten is for solid-solution hardening. Additions of nitrogen have

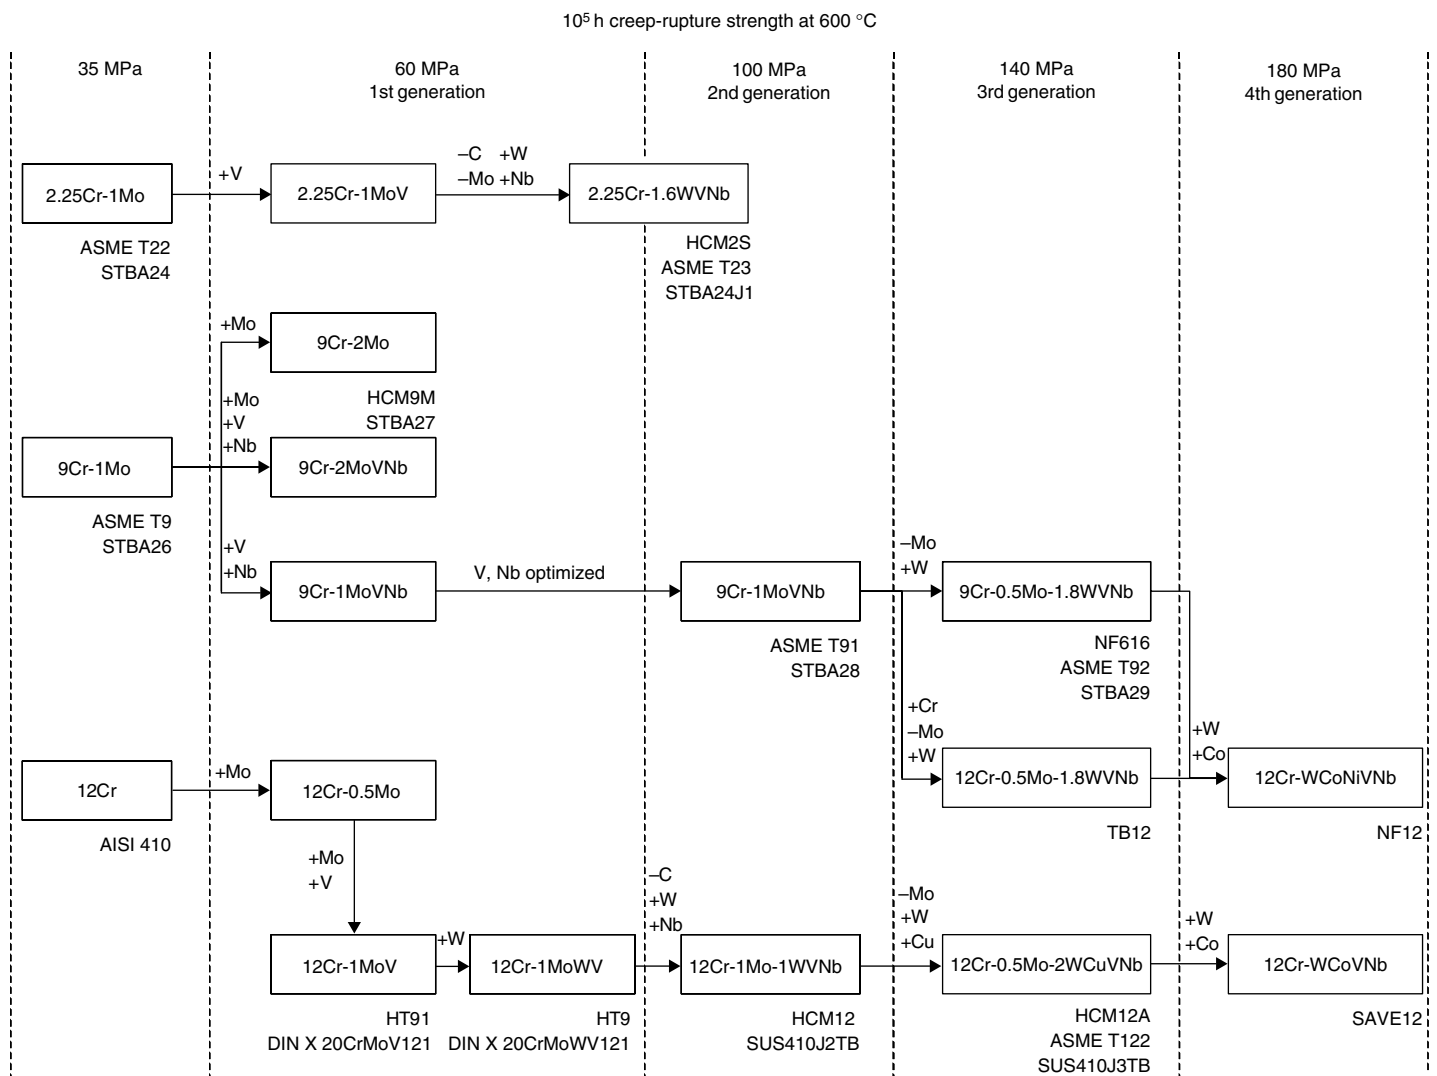

Fig. 5 The evolution of ferritic steels for boilers. Generations are categorized by the 10⁵ h creep-rupture strength at 600 °C. Source: Ref 7, 10

helped to stabilize the austenitic structure (Ref 7). The nominal compositions of austenitic boiler steels are given in Table 3. Also in Table 3 are some candidate high-chromium/high-nickel alloys and superalloys for higher-temperature applications in boilers and turbine components. Alloy 740 has resulted from the THERMIE program (Table 4).

Turbine Alloys

The materials used in turbine applications are subject to the stresses of high-speed rotating equipment.

Ferritic Rotor Steels. The primary alloy used in the industry for rotors up to 545 °C is 1Cr-1Mo-0.25V. For higher temperatures, 12Cr steels are needed for increased creep strength and corrosion resistance. The first of the 12Cr alloys

Fig. 6 Strengthening mechanisms and their effect on creep strength with time. Source: Ref 11

used for rotors was X21CrMoV121. The evolution of ferritic rotor steels from X21CrMoV121 for high- and intermediate-pressure steam turbines has loosely followed that of ferritic boiler steels. Alloy additions have been added and their amounts optimized, as shown in Fig. 8 (Ref 7). Nominal compositions of ferritic rotor steels are given in Table 5.

Turbine Blade Alloys. The ferritic steel 422 has been successfully used at temperatures up to 550 °C (Ref 7). Two possible ferritic alloys for use up to 630 °C are identified (Ref 14) and designated alloy C and alloy D. Alloy C is very similar to HR1200 and FN5 (Table 5). In the early 1990s, the Electric Power Research Institute identified four superalloys (M-252, Inconel 718, Refractory 26, and Nimonic 90) as good candidate materials for steam turbine blades (Ref 15). Although superalloys have been used extensively in gas turbines, they have not been evaluated with experience in steam turbines. An important consideration for the selection of these candidate superalloys was to have thermal expansion coefficients close to that of the 12Cr rotor steels. The four proposed superalloys are shown in Table 6, along with the ferritic alloys. Several candidate boiler alloys (Table 3) are also being considered for use in the turbine section (HR6W, alloy 230, alloy 617, and alloy 740) (Ref 16).

Bolting Materials. Bolting materials have requirements close to that of blade materials. Superalloys that have seen service in steam turbines as bolt materials are shown in Table 7. Of these, Refractory 26 and Nimonic 80A have seen the most service (Ref 7).

Corrosion in Supercritical Water

Steamside corrosion in supercritical power plants is important because of three factors (Ref 8):

- Section loss combined with high pressures can lead to component failures.
- Loss of heat transfer in water walls, superheaters, and reheaters due to the buildup of low-conductivity oxides. This leads to an increase in metal temperature that increases corrosion and creep.
- The buildup of thick oxides is much more prone to spallation, which increases the chance for tube blockages and steam turbine erosion.

Corrosion in steam has been studied intensively. Therefore, this review is limited to aspects that relate to supercritical conditions for the alloys of interest. Reference 17 lists a compilation of high-temperature steam oxidation publications since 1962 for advanced steam conditions; Ref 18 and 19 pertain to supercritical conditions.

McCoy and McNabb (Ref 18) examined several iron- and nickel-base alloys exposed for up to 22,000 h in supercritical steam (538 °C and 24.1 MPa, or 3495 psi) at the TVA Bull Run Steam Plant. They found that the corrosion rates of ferritic steels with chromium contents from 1.1 to 8.7% were all within a factor of 2 of each other. Higher chromium levels (17 to 25%) dropped the corrosion rate by an order of magnitude. This is consistent with findings at lower

pressures, where below 600 °C, the corrosion behavior is largely independent of chromium (2 to 12%) content (Ref 20, 21). The difference between 9% Cr and 12% Cr becomes significant at 650 °C (Ref 21, 22).

Paterson et al. (Ref 19) used in-plant measurements to compare the oxide scale thickness from superheater tubes and reheater tubes. The oxide scales were 45% thicker on the superheater tubes. Using the bulk steam pressures (P) experienced by the two types of tubing, it was calculated that the oxide growth rate was proportional to $P^{1/5}$. It was surmised that the pressure effect was due to differences in the partial pressure of oxygen at the different pressures. For example, using the STANJAN computer code (Ref 23), the oxygen partial pressure of steam at 593 °C derived from 200 ppb dissolved oxygen feedwater was calculated to be 1.91×10^{-5}

and 2.75×10^{-5} at 17.2 and 24.8 MPa (2.5 and 3.5 ksi), respectively.

The phase stability diagram for iron in water, as functions of temperature and oxygen partial pressure, is shown in Fig. 9, based on calculations by Gaskell (Ref 24) and including the predicted conditions by Paterson et al. (Ref 19). This diagram helps to explain the scale morphologies found on low-alloy boiler steels. Typically, the scales consist of several layers that correspond to the decreasing oxygen activity found within the scale closer to the metal. Hematite (Fe_2O_3) may form as a thin outer layer. A duplex magnetite layer forms under the hematite. The outer magnetite layer is Fe_3O_4 and grows out from the original metal surface. The inner magnetite layer is $(\text{Fe,Cr})_3\text{O}_4$ and grows inward from the original metal surface. The interface between the two magnetite layers

corresponds to the original metal interface (Ref 25). Wustite (FeO) may form under the magnetite layer. Wustite formation appears to be a function of chromium content, temperature, and water vapor pressure (Ref 26). Wustite formation is associated with an increase in oxidation kinetics and may be responsible for the transition from parabolic to linear kinetics that occurs after many thousands of hours of service (Ref 8).

Hematite formation is also associated with increased spallation during shutdowns, due to its large thermal mismatch with magnetite. In addition to the excess oxygen conditions of Fig. 9, hematite can also be formed due to a lowering of the amount of iron arriving at the outer scale, which has been attributed to the voids that form at the base of the scale after many tens of thousands of hours of exposure (Ref 27).

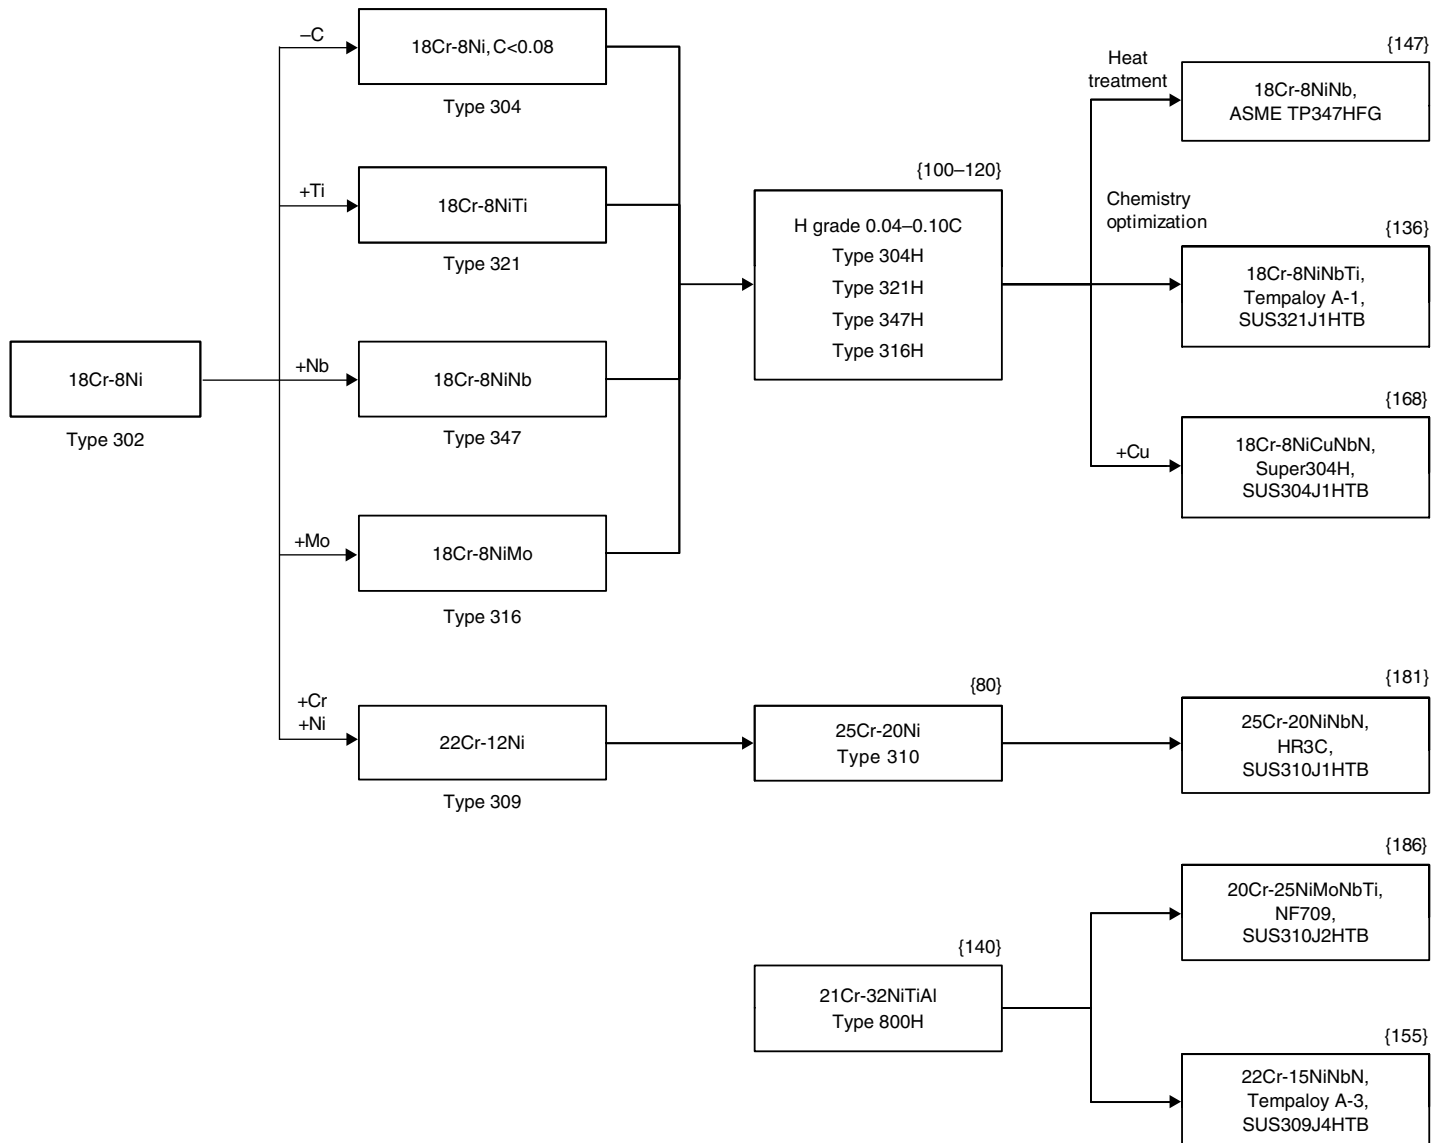

Fig. 7 The evolution of austenitic steels for boilers. {#} indicates 10^5 h creep-rupture strength at 600 °C, 2 Mpa. Source: Ref 7,10

Austenitic steels with 18Cr, such as 304 and 347, are similar but form a thin layer of Cr_2O_3 under the $(\text{Fe,Cr})_3\text{O}_4$ layer (Ref 28). The Cr_2O_3 layer is quite protective and substantially reduces the oxidation kinetics. With 25% Cr or more, the morphology changes to just Cr_2O_3 on the surface of the alloy (Ref 28).

Spallation is a common occurrence for both ferritic and austenitic steels. As a rule, only the outer layer of the oxides detaches for ferritics,

which can lead to small particle erosion of downstream components, including turbine blades. The thermal expansion mismatch between austenitic steels and their oxides is larger than for ferritic steels. So, the spallation of scales down to the bare metal is more common, and the larger particles can cause blockages of tubes, leading to short-term overheating failures of superheater and reheater tubing (Ref 27).

Efficiency

A discussion of the overall efficiency (or simply, efficiency) is helpful to understand the benefits of USC power generation. Efficiency is the ratio of energy output to energy input and is a function of many factors, for example, the thermal efficiency, the quality of coal, the condenser pressure, and the heating value (heat of reaction)

used. There are two main ways of quantifying the heating value of the fuel: the gross or higher heating value (HHV), and the net or lower heating value (LHV). Efficiency is a function of

the reciprocal of the heating value; that is, it is the energy-input part of the efficiency equation.

Water vapor is a combustion product for all hydrogen-containing fuels. The HHV is deter-

mined based on the final product water being condensed into water; the LHV is determined based on the final product water remaining a vapor (Ref 3). The HHV of a fuel can be directly determined using a bomb calorimeter, while the LHV of a fuel is usually calculated from the HHV using a formula (Ref 3) such as:

$$\text{LHV} = \text{HHV} - 23.96(\text{H}_2 \times 8.94) \quad (\text{Eq } 1)$$

where LHV and HHV are in kilojoules per kilogram, and H_2 is the mass percent of hydrogen in the fuel. Because HHV is typically used in the United States and LHV in Europe, it is important to recognize the differences between them when comparing efficiencies. Plant efficiencies in Europe are usually cited as three to five percentage points higher than in the United States; the use of LHV instead of HHV accounts for approximately two of these percentage points (Ref 2).

Benefits

The driving force for increased operating temperatures and pressures has been increased efficiency in power generation. Recently, an

Table 10 Cost calculations comparing subcritical and supercritical plants at 80% capacity

Total cost is on a 20 yr, constant dollar basis.

Cost categories, \$/MW/h	Subcritical	Supercritical, 566 °C	Supercritical, 593 °C
Capital	25.03	26.3	26.8
Operation and maintenance	6.2	6.3	6.3
Fuel	13.9	13.1	12.9
Total cost of electricity	45.1	45.7	46.0

Source: Ref 2

while increasing the steam pressure is less effective. Improvements in efficiency for the newer generation of SC and USC power plants are shown in Table 9, as compared to a subcritical 16.5 MPa/538 °C/538 °C plant with an efficiency of 37% (HHV) (Ref 29).

For reduced CO₂ emissions, calculations (Ref 30) indicate that a subcritical 37% efficient 500 MW plant burning Pittsburgh No. 8 coal would produce approximately 850 tons of CO₂ per kilowatt/hour. Ultra supercritical plants at 43 and 48% efficiency would produce approximately 750 and 650 tons of CO₂ per kilowatt/hour, respectively.

Calculations (Ref 2) indicate that factoring in the cost of CO₂ emissions is necessary for making SC and USC power generation cost-

effective, as shown in Table 10. In these calculations, the increased efficiencies are factored into the fuel savings, but the increased capital costs are more than the fuel savings. Factoring in the cost of CO₂ emissions, either by a carbon or CO₂ tax or by regulation, could shift the cost benefits toward the use of SC systems. This helps to explain why Europe and Japan (with CO₂ or energy taxes) have more ongoing construction of USC plants than does the United States.

Worldwide Materials Research

International materials research during the last 20 years has led to numerous new alloys for steam boilers and turbines and an increase in steam temperatures. Much of the efforts aimed at temperatures up to 650 °C is by improving on the ferritic steel 12Cr-1MoV. Major industrial research and development efforts in Japan, the United States, and Europe are briefly outlined in Table 4.

Corrosion in Cold Climates

Lyle D. Perrigo, U.S. Arctic Research Commission (retired)
James R. Divine, ChemMet, Ltd., PC

THE FORMS OF CORROSION encountered in cold climates and the methods of control are the same as elsewhere in the world, although frequently the intensity or rate of corrosion may vary significantly. The effect and impact of corrosion often differ significantly. Although temperatures are generally lower, other variables, such as higher dissolved oxygen concentrations, abrasion, isolated internal and external environments, salt deposition, and maintenance difficulties, can create aggressive conditions and result in high corrosion rates. On the other hand, low-temperature quiescent environmental conditions and slow oxygen diffusion rates can lead to the exhaustion of oxygen adjacent to metallic objects and a consequent reduction of corrosion. Corrosion measurements taken at docks and piers in southeastern Alaska lend support to these views (Ref 1). These special aspects are the focus of this article, while more detailed information can be found elsewhere.

Cold Climates

Arctic and *Antarctic* are terms used to identify parts of the world above and below the Arctic and Antarctic Circles ($66^{\circ} 33'$ north and south latitudes), respectively. Those lines do not define or include all geographic areas where cold-climate effects are prevalent, nor do the terms *subarctic* and *subantarctic*, which some define as

those parts of the world north and south of 60° latitude and running to the polar circles.

The geographic boundaries of the mission areas of the U.S. Army Cold Regions Research and Engineering Laboratory (CRREL) are used to define cold-climate areas in the Northern Hemisphere (Ref 2). The CRREL mission area lies north of line B in Fig. 1. Above line A, the approximate average temperature in the coldest month is -18°C (0°F) or lower, and above line B, the approximate average temperature of the coldest month is 0°C (32°F) or lower. Cold-climate corrosion conditions can exist in the lower latitudes but are likely to be limited in scope.

Similarly, two lines define where cold weather conditions are important in the Southern Hemisphere. The northernmost is the summer isotherm, where the mean temperature of the warmest month is 10°C (50°F). The polar front, or southern convergence, is the line between two well-defined water masses: near-freezing Antarctic waters to the south and warmer waters to the north. This boundary wanders between latitudes 50° and 60°S . It is detectable by a sudden change in temperature and salinity. The southern convergence line is shown in Fig. 2 (Ref 3). Cold-climate corrosion problems are found in the lower latitudes of both hemispheres in the higher altitudes of mountainous regions in other parts of the world (Ref 4).

Another factor influencing corrosion, and particularly corrosion control, is permafrost.

Permafrost is a term used to note the presence of frozen ground throughout the year. Most of the areas bordering the Arctic Ocean have continuous permafrost, which means that the entire area is underlain with frozen ground. Permafrost can be more than approximately 300 m (1000 ft) thick (Ref 5). South of the arctic continuous permafrost areas are discontinuous permafrost regions that contain patches of permafrost. The extent of permafrost in the Southern Hemisphere is not as well defined but does include all of Antarctica.

Corrosion Control Techniques and Costs

Using pipes and tanks as examples, corrosion environments exist both internally and externally to containment. Internal environments are those inside the systems and equipment and involve the fluids being handled in those systems. They

Fig. 1 Cold-climate areas in the Northern Hemisphere. For the coldest winter month above line A, the average temperature is -18°C (0°F) or lower, and above line B, the average temperature is 0°C (32°F) or lower. Source: Ref 2

Fig. 2 Location of the southern convergence, or polar front, (dashed line) marks an abrupt change in water temperature and salinity. Source: Ref 3

may be affected by external temperature conditions but are generally no different from those in the temperate climates. Internal corrosion can be controlled primarily by selection of materials, design, process control, internal coatings, and inhibition. The external environments are subdivided into three categories: atmospheric, buried, and submerged. The methods used to control corrosion in external environments typically include suitable materials selection, anticorrosion design principles, cathodic protection (CP) techniques, and application of protective coatings.

The total annual cost of corrosion in the United States was recently estimated to be 3.1% of the gross national product, which, for 1998, was \$276 billion (Ref 6). For additional information, see the article "Direct Cost of Corrosion in the United States" in *ASM Handbook*, Volume 13A, 2003, p 959–967. To establish a context for the impact of cold-climate corrosion, the cost in Alaska in 1997, using the value of 3.1%, would be slightly under a billion dollars per year. A detailed examination of corrosion control in the North would show added costs are associated with transportation, storage, weather constraints, ergonomics, and a number of other details. Thus, the percentage of the gross state product for Alaska, the Antarctica, the northern parts of Canada, Scandinavia, and Russia associated with corrosion is estimated to be in excess of 5%.

While the effect of cold-climate environmental impact on corrosion costs is not known exactly, designers, construction companies, operators, and maintenance people must recognize that these costs are significant. The need for corrosion control assistance by corrosion engineers with cold-climate experience is apparent.

Design

Engineers design systems, facilities, and equipment by using a combination of experience, available data and information, and calculations. Canadian and Scandinavian building specifications and standards recognize the need to apply different methods than those used in temperate zones. The author of design specifications for structures and equipment intended for cold climates needs to be cognizant of the unique requirements and not simply apply to national or industry standards that may not have consideration of cold climate within its scope. What follows in this section are examples of some of the major issues involved in designing systems with acceptable cold-climate corrosion performance. Topics include location, inappropriate measures, special factors, and ergonomics.

Location. Some of the highest marine corrosion rates in the world are found on offshore petroleum production platforms in Cook Inlet, AK, (Ref 7) where CP current densities of 376 to 430 mA/m² (35 to 40 mA/ft²) are typically required to protect the structure. These rates are twice as high as those in the North Sea and six times greater than those in the Gulf of Mexico,

despite the higher temperatures in the Gulf. The high rates are caused by high oxygen concentrations, abrasion from glacial silts, a tidal rise and fall of more than 9 m (30 ft), and the action of ice floes in the winter. Splash zone corrosion rates on docks are estimated to be as high as 762 to 889 $\mu\text{m}/\text{yr}$ (30 to 35 mils/yr) in the Aleutian Islands (Ref 1).

The literature on uses of CP to control corrosion in cold-climate marine environments is substantial (Ref 1, 8). One problem is that itinerant specialists, sometimes unfamiliar with cold climates, determine the performance of CP systems installed in remote and rural locations. Because impressed current CP systems require more attention to ensure proper operation than do sacrificial anode systems, the latter are generally favored in cold climates. Background on CP systems is found in the article "Cathodic Protection" in *ASM Handbook*, Volume 13A, 2003. The environment and temperature are factors in the capacity and efficiency of all sacrificial anode alloys. High-resistivity soils affect the design of underground systems in the cold regions. Further, sacrificial zinc anodes become passive in high-resistive soils in 3 to 4 years, while magnesium anodes often provide needed protection for much longer periods. A compilation of papers, standards, and articles describing CP applications, guiding procedures, and monitoring techniques was published in the early 1980s (Ref 1, 8). Many of these papers relate to problems and conditions in cold-climate areas of Alaska, Canada, and Norway.

Antarctic studies (Ref 9, 10) show that ISO standard 9223 (Ref 11) does not properly define the time of wetness (TOW) as a means to determine corrosivity at that location. See the article "Atmospheric Corrosion" in *ASM Handbook*, Volume 13A, 2003, p 196–209 for a discussion of the relevance of TOW. The studies concluded that significant corrosion was evident on samples exposed at temperatures below 0 °C (32 °F), while the criterion for estimating TOW of ISO standard 9223 is only for temperatures greater than 0 °C (32 °F). Salt deposits, consisting of chlorides and sulfates, play a significant role in promoting corrosion under cold-climate conditions by being deliquescent and forming nearly invisible films of moisture. Except in the interiors of the cold regions, such as the dry valleys of central Antarctica, atmospheric corrosion rates in the cold regions can approximate those in more temperate zones. Ratcliffe (Ref 12) has noted extensive amounts of external corrosion on metal buildings, particularly under the insulation on those structures. In addition, acceleration of external corrosion due to abrasion from wind-driven glacial silt has been observed near the Antarctic coast. Figure 3 shows what occurred on the external surfaces of a Quonset hut. The costs for repairs to such structures are high because of the remoteness of the area and the limited periods during which work can be performed (Ref 12).

While atmospheric corrosion rates in inland areas of the cold-climate regions are low

(Ref 13, 14), they are definitely not zero. Industrial coatings (epoxies, urethanes, and alkyls) are used to ensure adequate performance of materials and facilities (Ref 1). If effective performance is to be realized, they must be applied and cured at 10 to 32 °C (50 to 90 °F). Even summer temperatures may not reach the lower acceptable temperature. A temporary plastic-covered framework with high-velocity air heaters may be needed to provide the required temperature for surface preparation, application, and curing. This will increase time and costs. Extra emphasis must be placed on safety in this artificial environment.

Inappropriate Measures. Another factor to consider is that common techniques used to compensate for cold-climate effects may have adverse impacts on corrosion prevention. For example, utilidoros are underground or above-ground structures that protect utilities from cold weather while providing general access for operations and maintenance. Underground utilidoros may flood due to piping failures, overhead snow melts, or stream overflow during ice breakup and jamming in the spring. When thermal insulation is soaked, the pipes can suffer from corrosion under insulation (Ref 15, 16). The designer should specify immersion-service coatings for external piping surfaces used in underground utilidoros to limit these effects, in accordance with NACE International recommended practices (Ref 16).

Marine atmospheres, such as those found in the Aleutian Islands, often induce high corrosion rates. Coatings may fail rapidly, and fasteners used in the installation of building siding must be properly selected and seated, or large blisters can be expected under the coating in 2 to 3 years (Ref 1). Special marine coatings must be used to avoid corrosion problems, especially in facilities that may not be accessible most of the year (Ref 15).

Industrial facilities and larger municipalities in cold regions often have most of their equipment in heated spaces, where maintenance can be done in a timely manner. In smaller facilities, however, equipment that requires some protection from the elements may be in unheated

Fig. 3 Corrosion on a metal building in Antarctica. Corrosion is also evident on the steel vise.
Source: Ref 12

enclosures. Because access is difficult, maintenance is often delayed until conditions are more favorable. A common result is that leaking fluids, although freezing quickly, will still soak insulation and ultimately cause corrosion problems.

Special Factors. Anticorrosion design or corrosion control design describes the use of layout, location, joining practices, orientation, avoidance of liquid holdup areas, and related topics to minimize corrosion (Ref 17). Although these techniques have been known for decades and are effective, these principles may not always be applied. User and operating organizations should require engineering design groups to address anticorrosion design factors, because of the potentially severe consequences of poor design in cold climates.

Two corrosion control design problems, often overlooked because they are not considered as corrosion issues, involve accessibility and safety. Corrosion control personnel must be able to reach operating systems and facilities and to use monitoring equipment to be effective in their work. Maintenance crews can do their jobs only if they have ready access to all items that may require repair or replacement during the operational lives of plants and facilities. Providing access in cold climates involves ways to avoid problems created by snow and ice, the effects of low temperatures, and the impact of winter darkness.

Gratings used around fuel storage tanks and the stairs to living quarters should be designed and constructed so that there are no crevices or holding areas that will retain deicing chemicals or salt-laden moist marine air (Ref 1). Chemicals in such crevices lead to accelerated corrosion, which in turn results in unsafe conditions. Dike systems surrounding tanks often trap melting snow and ice in the late spring. Water in the drains installed at low points in the diked area can remain frozen when other, more exposed ice and snow melt. The trapped water rises to the base of the tank, filling any crevice between the sand and the tank bottom. This is especially troublesome if oiled sand is used beneath storage tanks, because oiled sand impedes effective use of cathodic protection.

Ergonomics, the study of human factors or man-machine interface issues, addresses conditions that affect corrosion control work in cold weather and remote areas. Three factors to be considered in designing equipment and facilities are:

- Equipment used in monitoring work or to support such activities must be available when needed (Ref 1, 17). In cold regions, this may mean extensive warm-up periods or special arrangements to place the needed items in remote locations. The equipment must function reliably and in an effective manner, to avoid safety problems or costly delays. Electronic instruments must be operated within the temperature limits for which they are designed and calibrated. This means they may

need to be housed in a warmed, insulated container or operated from a warm vehicle.

- It takes longer to inspect equipment, study failures, and conduct monitoring operations undertaken outside in cold weather. Designs should allow extra space for movement in bulky clothing, limit the number of monitoring stations located outside, and arrange equipment so that only a few movements are needed to make measurements or observations (Ref 18).
- Because corrosion coupon locations, sampling ports, and other monitoring equipment and facilities are located outside, the design must allow equipment to be operated with heavy mittens, bulky clothing, and limited visibility.

Transportation and Storage

A common cause of corrosion in cold climates is improper transportation and storage practices (Ref 19, 20). Most equipment and materials used in cold climates for construction, operations, and maintenance are transported by barges and ships from temperate-zone ports. Transportation routes through polar regions are matters of concern to corrosion engineers for three reasons:

- Several have notoriously bad weather and sea conditions.
- Many are open only for limited times each year.
- Special arrangements are needed to ensure that transit and storage do not adversely affect the corrosion performance of the cargo (Ref 1).

The spalling seen on the precast concrete panels in Fig. 4 occurred after three years. The panels were exposed to seawater from wave action during shipment. Poor packaging can be costly on the return route as well. An example is pumps that were shipped to Seattle after use in the *Exxon Valdez* oil spill cleanup in Prince William Sound in 1989. These items were placed in containers with wooden floors that allowed moisture to reach the pumps. With no vapor-phase inhibition, corrosion of the electrical equipment occurred in the containers. Extended storage near the docks after arrival in Seattle, with no inspection or remedial action, led to a total loss of the equipment (Ref 1).

Construction

Corrosion problems resulting from cold-region construction practices confront construction and maintenance personnel (Ref 17). Cognizant contractor personnel require special corrosion education courses, training, and certifications to eliminate such problems. Such training is required by Alyeska Pipeline Service Company, which requires inspectors to have

NACE International certifications. Of great importance is how changes in design, procedures, or materials will impact corrosion and corrosion control of the completed facility (Ref 1). Detailed briefings at prejob conferences avoid later conflicts and produce excellent results.

Frequent checks of construction projects by a corrosion engineer and maintenance supervisors can be of benefit in two areas. First, observations may supplement the work of the project manager and inspectors. Second, the acquisition of general information will be useful after the system or facility begins operation. For the latter, observations made by a corrosion engineer during construction are particularly helpful in establishing a background to assess problems and conduct failure analyses. Maintenance personnel find that such observations create an awareness that makes future repairs easier and quicker. Some contractors discourage visitors on the basis that their questions distract personnel and cause delays. Nevertheless, the possible benefits in cold regions are significant. Giving corrosion engineers and maintenance supervisors access to make periodic observations should be included in the contract language.

Types of common on-site practices that may cause corrosion problems in cold regions are briefly discussed here. First, the use of readily available local rock and gravel, rather than adherence to the size and type specifications for gravel and rock, often occurs, which may affect the performance of buried, coated piping systems. Freeze-thaw cycles cause the ground to move. The irregular fill may increase the chances of mechanical coating damage, leading to local corrosion. Variations in the fill can create anodic and cathodic areas along the pipe that contribute to galvanic corrosion.

The short construction season and remote location create pressure to make substitutions when the needed and specified parts are not available or are damaged in transit. Substitutes often do not perform well and lead to early failures. Another problem caused by short construction seasons is a tendency to save time by relaxing the quality of surface preparation work

Fig. 4 Spalling on precast concrete panels occurred in three years after exposure to seawater during shipment. Reinforcing bars are exposed.

before coatings are applied. Less rigorous procedures lead to shorter service lives for the facilities (Ref 21).

Infrequent shipment to isolated sites, a common occurrence in cold regions, can also play a role in corrosion prevention work. Careful planning is necessary prior to construction to ensure that the correct materials are available when needed. Such an approach will minimize tendencies to substitute parts constructed from materials with poor corrosion performance. Proper storage of coating materials and other moisture- and temperature-sensitive materials at the site is required. The benefits of proper storage in a centralized facility are negated if these materials are placed in vehicles where temperatures may drop below critical temperatures. The use of coating materials after such handling will lead to poor coatings and inadequate corrosion protection. It is also necessary to ensure that work is done when the needed equipment is available. For example, cranes are not allowed to operate at very low temperatures.

Often, cold-climate building materials use precoated, insulated metal sheets for exterior (and often interior) walls. A lack of care in installing them can lead to early coating and panel failures.

Operations and Maintenance

Some corrosion problems arise from improper operations and maintenance practices. A lack of care in snowplowing to clear walkways and parking areas can jam snow and ice against the metal siding of buildings, opening seams and damaging coatings. When this occurs, moisture can enter and cause corrosion of the substrate, exposed by cracks and chips in the coating. The moisture behind the siding creates two problems. First, this moisture provides a medium for freeze-thaw damage that accentuates the mechanical damage. In addition, it may result in counterbuckling the external surface or damaging the wall beyond the insulation. Another effect is corrosion of the internal surface of the siding, because this surface is rarely coated, and the insulation keeps the surface wet. Maintenance personnel can take action to avoid such damage. Placing bollards near buildings where snowplows operate limits the approach of those vehicles.

Often, operating and maintenance personnel in cold regions find themselves with facilities and equipment that were designed without the use of anticorrosion design concepts (Ref 18). These systems have crevices and places where fluids stay in contact with the metals for appreciable periods of time. Sometimes, these problems can be avoided by simply creating ways to drain fluids from the holdup areas.

Minor changes to the exterior surface of an existing tank, such as installing a drip skirt, can

limit the amount of corrosion. However, the metal should be joined to the tank with a continuous weld to prevent fluids and/or snow from reaching the tank bottom. If not, the interfaces between the bottom and the support members become sites where accelerated corrosion would occur. Channels and angles oriented with their webbing upward can collect snow and rain, leading to corrosion. Problems can be avoided or reduced by drilling a few holes through the webbing of these members, to serve as drains for any water that may temporarily collect.

ACKNOWLEDGMENTS

The authors gratefully acknowledge information provided by Guy Ratcliffe, Australian Antarctic Division, Kingston; and other input from Janet Hughes, National Gallery of Australia, Canberra; and George King, Sandringham, all of Australia, who provided extensive amounts of information about the effects of sealants on atmospheric corrosion in Antarctica. Winston Revie, CANMET, Ottawa, Canada, chaired a symposium on cold-climate corrosion at the annual NACE International conference in 2002 that provided the authors with access to additional corrosion information.

Corrosion in Emissions Control Equipment

William J. Gilbert, Branch Environmental Corp.

CORROSION PROBLEMS and materials selection for emissions control equipment can be difficult because of the varied corrosive compounds present and the severe environments encountered. Therefore, a number of the more common emissions control applications are discussed. More detailed information on the applications is available in the references cited at the end of this article.

Flue Gas Desulfurization

By far the most common cleaning application for flue gases is flue gas desulfurization (FGD). This section discusses the selection of materials of construction for FGD systems. More information on corrosion in FGD systems is available in the article "Corrosion of Flue Gas Desulfurization Systems" in this Volume.

These systems were introduced in the late 1960s to meet tightening restrictions on the release of sulfur emissions. The oil shortage of the mid-1970s and subsequent oil price increases led to the increased use of coal in new and renovated power plants. In virtually all cases, this meant the potential for increased sulfur emissions, so many more FGD systems were needed.

Flue gas desulfurization systems typically use wet scrubbing units with lime or limestone slurries for sulfur dioxide (SO_2) absorption. Initially, it was thought that the relatively mild pH and temperature conditions found within most of these systems would not present a significant corrosion problem. This was soon found not to be the case. Because the FGD system constituted up to 25% of the total capital and operating expenses of the power plant, it was imperative to determine the causes of the failure of the material.

Environment. The gases encountered by the FGD system are hot and contain SO_2 at significant levels, some sulfur trioxide (SO_3) as a result of the oxidation of SO_2 at high temperatures, and fly ash. Initially, these gases may be sent to a dry-dust collector, such as an electrostatic precipitator or fabric filter baghouse, for fly ash removal. The gases typically enter a wet scrubber (a venturi with separator) and are quenched as SO_2 is absorbed. The components that often have the severest problems, however, are the outlet duct and stack. Here, the

condensates are more acidic, the gases are highly oxygenated, and the presence of chlorides and fluorides can cause serious corrosion problems. Nevertheless, throughout the entire system, corrosion can occur to various degrees and because of various factors.

Corrosion Factors. Four basic factors affect the severity and type of corrosion that occurs.

pH. The result of the reactions that take place within the scrubber is a slurry with a typical pH of 4 to 5. This is desirable, because it allows for good absorption of SO_2 and is acidic enough to reduce scale formation. Local pH values as low as 1 may exist from the concentration of chlorides entering the makeup liquid (with contributions from fluorides). Low-pH conditions with the presence of chlorides and fluorides limit the use of carbon steels, stainless steels, and a number of higher-nickel alloys (Fig. 1).

Gas Saturation. The dry flue gas is not severely corrosive. However, when the gas reaches its dewpoint, sulfuric (H_2SO_4) and sulfurous (H_2SO_3) acids can form. In addition, hydrochloric acid (HCl) is produced because of the presence of hydrogen chloride (formed at the elevated temperatures of combustion) plus the condensing water vapor. Again, carbon and stainless steels are affected.

Temperature. The problems caused by temperature excursions lessen the corrosion-resistant properties of synthetic coatings, fiberglass-reinforced plastics (FRPs), and thermoplastics, possibly to the point of complete destruction at high temperatures. This affects metals to a lesser extent but still can degrade the materials.

Erosion generally occurs as a result of fly ash carried by the gas impacting a surface in a relatively dry area of the system or the liquid slurry impinging on a wetted surface. In either case, areas susceptible to corrosion attack are produced.

General Materials Selection. An easily overlooked but critical aspect of materials selection is the ability of the manufacturer to construct the equipment with correct fabrication techniques. In particular, with regard to the use of high-nickel alloys, the welding recommendations of alloy producers should be precisely followed to maintain the corrosion resistance of the materials (Ref 2). This is, of course, true

for any type of fabrication. The most careful materials selection process can be negated by poor fabrication practices.

Metals. Where pH is neutral or higher, austenitic stainless steels (types 304, 316, and 317, L grades preferred) perform well even at elevated temperatures. If pH is as low as 4 and chloride content is low (less than 100 ppm) but temperatures are above approximately 65 °C (150 °F), then Incoloy 825, Inconel 625, Hastelloy G3, and alloy 904L (UNS N08904) or their equivalents are usually acceptable. Table 1 lists compositions of alloys commonly used in FGD systems.

When chloride content is up to 0.1% and pH approaches 2, only Hastelloys C276, G, and G3, and Inconel 625 can be successfully used. The other alloys mentioned previously would be subjected to pitting and crevice corrosion. If a region is encountered with pH as low as 1 and chloride content above 0.1%, one of the only acceptable alloys is reported to be Hastelloy C276 or its equivalent. Generally, the higher the molybdenum content of an alloy, the more

Fig. 1 Minimum levels of chloride that cause pitting and crevice corrosion in 30 days in SO_2 -saturated chloride solutions at 80 °C (175 °F). Source: Ref 1

severe the corrosive environment it can withstand in the FGD system (Ref 3).

Nonmetals. Fiberglass-reinforced plastics can be used in almost any application in which temperatures do not exceed 120 °C (250 °F) (preferably 95 °C, or 205 °F), regardless of whether there are high chlorides or low pHs. The best choices would be premium grades of vinyl-ester and polyester resins. Polypropylene, chlorinated polyvinyl chloride (CPVC), and other thermoplastics can be used in such applications as mist elimination, where temperatures are lower. For example, polypropylene can withstand 80 °C (175 °F). Rubber linings can also be used where temperatures are suitable and mechanical damage can be avoided.

Waste Incineration

In a number of ways, the problems associated with materials for incinerator off-gas treatment equipment are similar to those of FGD systems. Depending on the wastes being burned, however, significantly higher gas temperatures as well as more varied and more highly corrosive compounds may be encountered. Materials selection can often be more demanding.

The importance of incineration for the treatment of domestic and industrial wastes has increased as sanitary landfills are less available and more expensive. At the same time, environmental safety regulations have limited the use of deep below-ground and sea-disposal sites for untreated wastes.

Incineration provides a viable, although not inexpensive, alternative that reduces the volume of solid waste by as much as 90%. The remaining material is generally inert and will not leach chemicals into the surrounding aquifer. The by-products of combustion contain gas and particulate contaminants that can be filtered or scrubbed. Incinerators are used to burn municipal solid waste, biomaterials such as hospital waste, low-level radioactive waste, industrial chemical waste, and sewage sludge. In general, the off-gases can be classified according to their corrosiveness in descending order as: industrial

chemical, hospital, municipal solid, and sewage sludge.

Industrial Chemical. These gases are characterized by extremely high temperatures (1000 °C, or 1830 °F, is not uncommon) used to destroy the chemical. This can result in the formation of halogenated compounds from chlorine or fluorine in the raw material. Hydrogen bromide, sulfur oxides, phosphorus compounds, and oxides of nitrogen can also be produced, depending on the composition of the waste treated.

The typical treatment system uses a gas quench to saturate and cool the gases, a wet venturi scrubber (if particulates pose a problem), a packed tower absorber, exhaust fan, ducting, liquid piping, and liquid recirculation pumps. Figure 2 shows a standard system arrangement, and installed equipment is shown in Fig. 3.

Because of high temperatures, the presence of chlorides, and the fact that the gas becomes saturated with water vapor within the first-stage quench, very few materials have been successfully used for the quench construction. The major problem with many metals is not uniform attack but local pitting and crevice corrosion. In particular, chloride stress-corrosion cracking severely affects austenitic stainless steels.

The materials that perform well include Hastelloy C276, Inconel 625, and sometimes titanium for the high temperature. These materials have been used in other critical areas of the treatment system, such as fan wheels,

dampers, liquid spray nozzles, and piping. Multiple-year service life has been reported with these alloys (Ref 4).

Refractory linings for the quench have been used with some success. Alumina or selected carbide bricks can be installed. Because the brick is an insulating material, the outer-wall temperature is low enough to allow the use of carbon steel, such as A285 grade C, for the structural outer components. Steel must be protected by using an epoxy or elastomer lining to prevent corrosion of the steel vessel. This can sometimes prove to be a more economical alternative to the use of high-nickel alloys, especially on larger-diameter systems. Because care must be taken to avoid thermal shock that can fracture the refractory material, refractory linings are usually employed on larger systems with slow start-up times rather than on the smaller hazardous waste incinerators, where batch operation is often the rule.

**Fig. 2** Schematic of a general scrubber system arrangement**Fig. 3** A stainless steel venturi tube scrubber separator. Courtesy of Branch Environmental Corporation

Following the quench, temperatures are typically less than 95 °C (205 °F), but the price of satisfactory materials is increased. The materials used will often be those recommended for the chemical industry that produce the same chemicals as those expected in the gas. For example, phosphoric acid may readily be handled by using type 316 stainless steel in the scrubber following the quench.

Because the temperatures are relatively low, the concentrations of contaminants are low, and because cost is a design factor in pollution control equipment, it is not unusual to see FRP in the final equipment stage. That is, scrubber housings, pump bodies, and even fans can be made of FRP. A premium polyester or vinyl-ester resin can withstand even the most severe corrosive atmospheres at these milder temperatures. Even the presence of glass-attacking fluorides would not necessarily preclude the use of FRP. Synthetic veils are used to replace glass veils within the resin layers closest to the internally exposed surfaces.

Recirculating fluids, often alkaline because they are used to scrub acidic gases, can often be handled satisfactorily by type 316 stainless steel, fluoroplastic-lined pipe (for example, Teflon lined steel pipe), FRP, or CPVC. The choice is often based on plant preference: the metal pipe for mechanical strength, the metal pipe with plastic liner where more aggressive chemicals are present, or FRP/CPVC where cost is the most important consideration. In case the caustic feed system fails to operate, examination of the possible occurrence of a low-pH condition should also be considered. In many cases with high chlorides, this could result in pitting or damage to type 316 stainless steel.

Fiberglass-reinforced plastic ductwork is used to transport the gases in the milder-temperature areas of the system. Because polypropylene exhibits good resistance to most of the corrosives usually encountered, it is used for tower packing, mist eliminators, and spray nozzles. It is a particularly good choice for environments having the potential for severe fluoride attack.

Caution must be exercised when using plastics in the system following the quench. If the quench loses its liquid and there are no safeguards, a major part of the downstream equipment may be destroyed. Temperatures are typically monitored so that an emergency cooling liquid is injected into the quench to prevent disastrous temperature excursions if the normal liquid source is lost.

A more conservative design approach is to use a high-nickel alloy for the equipment directly downstream of the quench. In any case, this question must be addressed during the design phase of any incineration project.

Hospital Waste (Biowaste). The emission gas is in a lower temperature range (approximately 250 °C, or 480 °F) than for chemical incineration and can be handled by alternate technology such as a dry flue gas system. Where the gas is kept dry and above its dewpoint (the HCl dewpoint), carbon steel construction is

very common. Where fabric filter dust collectors are included, they are usually made of steel, although some collectors are constructed of type 316 stainless steel to avoid rust or corrosion.

Where further cooling is required, the wet-dry interface will become very corrosive as the HCl is exposed to moisture. Following the particulate collection system, it would not be unusual to have a secondary quench stage that is made from Hastelloy C276 or equivalent types of materials. Once the temperature is reduced, the final scrubber will often be made of fiberglass, using vinyl-ester resins, polypropylene internals, and thermoplastic pipe.

A fan for such systems is usually an epoxy-coated steel with a stainless steel impeller. Where high levels of chloride are suspected the impeller may be constructed out of Hastelloy C.

Low-Level Radioactive Waste. In the nuclear power industry, waste materials such as rags and clothes are treated as low-level radioactive waste. While containing little or no radioactivity, they must be treated separately from general waste. To reduce the handling volume of this material, a small incinerator can be used that destroys the combustible portion of the material, leaving behind approximately 5% residual ash.

The gases present in a typical incinerator of this type are very similar to those of a hospital waste incinerator, although the chloride content is usually lower. The component materials would generally be the same.

Municipal Solid Waste. The by-products of municipal solid wastes can be similar to those found in chemical incineration. However, the levels of the contaminants—chlorides, for example—are always much lower. Today, the operating temperature for many of these systems is close to 1000 °C (1830 °F) in the incinerator itself. For conservation, there will almost always be a wasteheat recovery system. This is usually a wasteheat boiler to generate steam or hot water. This results in an exit gas temperature that is typically in the 260 °C (500 °F) range. The requirements for burning these wastes, which contain large portions of cellulose, result in lower off-gas temperatures than those for chemical incineration.

Nevertheless, corrosion problems are severe, and material choices are similar to that of industrial chemicals incineration. Reference 5 provides a ranking of metals based on corrosion tests in this service. Reference 6 shows the results of corrosion tests for a very wide range of alloys in six distinct incinerator system zones.

Sewage Sludge. Burning of sewage sludge presents the least corrosive discharge of the four types under discussion. This can be attributed to limited halogen compounds in the gas and lower temperatures (typically 315 to 650 °C, or 600 to 1200 °F) compared to industrial and hospital waste incinerators.

Types 304 and 316 stainless steels are suitable for construction in most areas of the system, including the quenching area, whether as a separate quench or part of the wet scrubber.

Again, FRP, thermoplastics, and lined carbon steel can be used in the cooler regions. Typical materials are epoxy-coated carbon steel for the sump and lower portion of the scrubbers, with type 316 stainless steel used for portions where critical dimensions must be maintained, such as impingement trays.

The predominant contaminants in the environment are sulfur compounds, which may be present either as reduced sulfide compounds (H₂S plus mercaptans) or sulfur dioxide, depending on the operating temperatures within the sludge incinerator system. Usually, compounds are converted to sulfur dioxide prior to the scrubber. Chlorides can exist, but they normally originate from the water used for makeup. Their presence sometimes requires the use of high-nickel alloys for such components as fan wheels and pump impellers.

Erosion can be a significant problem in any of these systems. It can wear down critical moving mechanical components and equipment walls at points of liquid or gas impingement. It can contribute to corrosion. See the article "Gaseous Corrosion-Wear Interactions" in *ASM Handbook*, Volume 13A, 2003.

The erosion effects are not as severe as in FGD treatment equipment, but there are a number of areas of concern. The venturi throat and spray nozzles can suffer abrasion. Fan wheels and pump impellers, however, are usually the most critical areas in these systems. High-nickel alloys are used. Rubber lining can also be used, although generally not on fan wheels. Fiberglass-reinforced plastic can also be fabricated with silicon carbide impregnation for increased abrasion resistance.

Bulk Solids Processing

Bulk solids processing includes grain handling, foundries, coal handling, pneumatic conveying systems, and spray-drying systems, where there is the need to collect dust for air pollution control. In every case, fine particles of dust can become entrained in the exhaust air and must be removed prior to discharge of the air. The three most common types of dust collection equipment are fabric filters, electrostatic precipitators, and wet scrubbers.

Fabric Filters. The selection of materials of construction varies with the industry, but the dust handled is generally not severely corrosive. Carbon steel is the most common material in the vessel itself. The fabric used in the collector varies. The manufacturers of fabric filters have experience with selection for a specific application, so their expertise should be used in evaluating the initial and maintenance costs of alternate fabrics. Typically, most bulk-handling applications can be managed with the use of polypropylene for the filter bags. Currently, its cost is close to that of cotton filter bags, it does not rot when wet, and it offers relatively good corrosion resistance. The primary limitation is temperature.

Fans and stacks located downstream from a bulk filter are normally constructed of carbon steel. Because most of the dust has already been collected before it reaches this point, abrasion is not a major concern in the design of the downstream components.

Electrostatic precipitators are applied to a bulk solids application where high performance is required. This normally occurs in relatively dry services with inert particles. As such, the materials of construction are typically carbon steel.

Wet scrubbers are often used where the solids being handled are more reactive. For example, if there is a potential for an explosive mixture of the dust with air, the wet scrubber eliminates this problem. Wet scrubbers are also versatile and can simultaneously remove dust and gas.

The initial cost of scrubbers is partially determined by the need to recirculate a water-based solution. Care must be taken to ensure that this solution does not become corrosive or, if it does, to select the proper materials.

General nuisance dust collected by a scrubber does not cause a direct corrosion problem. Instead, the problems arise because of the need to minimize the wastewater from the scrubber. For example, if the inlet air is at ambient conditions, the scrubber will evaporate 122 L/h (31.8 gal/h) for every 10,000 m³/h (5889 ft³/min) of air flow. If the quantity of solids captured requires only 10% of the evaporation rate as a liquid bleed rate, then the dissolved solids in the water will be concentrated by a factor of 10. Thus, 200 ppm of chloride would suddenly become 2000 ppm of chloride. This is sufficient to cause corrosion concerns.

In most cases, fiberglass is used where abrasion is not particularly severe. In other cases, carbon steel is used, particularly for coal handling and other applications where abrasion is present.

Spray Dryers. Spray-drying applications typically require stainless steel. Either type 304 or 316 is used, depending on the particular compound being collected. The use of stainless steel arises from the need for product purity. Because the slurry is usually returned to the spray dryer, care must be taken to avoid potential corrosion problems.

Chemical and Pharmaceutical Industries

Chemical process and pharmaceutical industries experience a wide variety of corrosion problems. Many of the compounds used have severe effects on materials. For air pollution control equipment, the concentration of the compounds in the air (or liquid) is much lower than in the normal plant process flow. One of the differences of process operations compared to air pollution control is the operating pressures. Many chemical reactions are carried out under high pressures (several atmospheres) in reactors

to improve economics or yield. However, in ventilation systems, the gas will be at atmospheric pressure, so more economical materials that do not require the mechanical strength to handle high pressure can be selected.

Many of the clean-up systems used in chemical and process plants are fabricated from fiberglass, because FRP has low initial cost and good corrosion resistance in a wide variety of services. The corrosion resistance of FRP is a function of both the resin content and the specific resin used in the laminate.

Chloro-Alkali Plants. The production of chlorine results in severe corrosion problems. Quantities of chlorine in the effluent gas are normally scrubbed using dilute caustic solutions. Specific types of resin must be employed for the FRP used in this very difficult application. Vinyl-ester resins are most commonly used to handle chlorine and chlorides. In addition to using a high-performance resin, the inner glass reinforcement is usually replaced with a synthetic veil to provide additional protection and to avoid any attack by hypochlorite or caustic on the inner liner. The fiberglass is used for the scrubbers handling chlorine removal, ductwork, fans, and stacks; even recycle pumps are manufactured of this material.

Where heat exchangers are used in the recycled solution, fiberglass is obviously not a practical material because of its low heat-transfer coefficient. For dilute hypochlorite solutions, such alloys as Hastelloy C276 or Inconel 625 have been used. Graphite can be used if the proper binder is selected. With the high heat-transfer coefficients of plate heat exchangers, constructions of Hastelloy C276 can be economical.

Polyvinyl chloride (PVC) or high-temperature PVC (CPVC) is another material that performs well in this service. These materials are sometimes selected for small units or for ductwork construction.

Nitric Acid Plants. In nitric acid (HNO₃) manufacture, stainless steel is the most common material of construction. Concentrated HNO₃ will affect many of the nonmetallic materials. Fiberglass-reinforced plastic is not as common or as easily accepted.

Type 304L stainless steel or CPVC can be used for many ventilation systems. Fiberglass-reinforced plastic could also be used when the acid is being neutralized. Relative costs are shown in Fig. 4. Because the cost of stainless steel is still relatively high compared to that of FRP, FRP should be considered where very dilute acid concentrations are involved. Type 304L stainless steel remains the best where high concentration and return to the process are involved.

In many cases, HNO₃ manufacture also produces oxides of nitrogen. Nitric oxide (NO) and nitrogen dioxide (NO₂) would be handled by the same materials of construction. Most commonly, NO and NO₂ are removed from the air by using either scrubber systems or selective catalytic reduction (SCR).

With scrubbers, the recycled solution becomes a dilute HNO₃ solution. A special wet-phase catalyst has been developed for use in this service. Type 304 stainless steel is used for portions of the vessel, although fiberglass can be used if the concentrations are very low.

In other HNO₃ facilities, SCR is used to eliminate the residual oxides from the air. The catalyst itself is normally a ceramic honeycomb structure with semiprecious metal oxides applied to the surface. These materials are selected by the manufacturers and would be compatible with stainless steel components, which are typically type 304L stainless steel, that are selected for ductwork, fans, and other auxiliaries.

Sulfuric Acid Plant. The most common problem area in emissions control equipment in a sulfuric acid plant is where acid mist is collected by fiber bed mist eliminators. Such units employ a glass mat held inside of a vessel operating at low velocities to remove submicron mists. Fiber bed unit shells for H₂SO₄ are either type 316 stainless steel or alloy 20Cb3. The relative economics suggest the use of type 316 stainless steel, although it may suffer a small amount of attack.

Alloy 20Cb3 can be used for most ranges of acid that would be encountered in air pollution control systems. Type 316 stainless steel can be used if the solution is weak enough. Also, if

Fig. 4 Relative costs of scrubber materials. FRP, fiberglass-reinforced plastic; PVC, polyvinyl chloride

the temperatures are low enough, FRP should be considered. It is best to obtain coupons of the materials and to conduct some initial testing at dilute conditions before making a final decision. The industry practice is to use more and more FRP on these inorganic acid applications because of the low initial cost.

Sulfur Dioxide Service. Sulfur dioxide has requirements similar to sulfuric acid, even though the initial solution formed is usually a neutralized salt; that is, SO_2 is normally absorbed using an alkali solution such as lime or caustic. The solution formed is a sodium or calcium sulfite/sulfate mixture. It can be handled at low temperatures in fiberglass and at higher temperatures in type 316L stainless steel.

Because most of the SO_2 gas is removed in the air pollution control equipment, the downstream equipment can often be handled using liners rather than expensive alloys. In fans, an epoxy coating can be applied to the housing. For the wheel itself, a solid alloy is recommended because of the high speed involved. The combination of an epoxy liner and a stainless steel wheel can cost 25% less than a totally stainless steel fan.

Discharge stacks are often treated in the same manner. Where the stacks are large enough, a coating can be applied to a steel stack. Of course, the first choice may be a FRP stack if the temperature is low enough, because maintenance is eliminated. More information on materials of construction for the chemical processing industry is available in the articles on specific chemicals in this Volume.

The Fertilizer Industry. Several severe problems can occur in the manufacture of fertilizers. Trace quantities of fluorides in phosphates result in the formation of HF and tetrafluoride in the gas. Although these can be scrubbed out, the resulting solution is extremely corrosive to most metals and fiberglass.

The most common solution is to use FRP with synthetic veils rather than a glass lining. The FRP resin itself is not affected by the HF, but the internal glass could be. A small pinhole leading to the glass can result in catastrophic attack. This is avoided by substituting a synthetic veil for the glass.

Fiberglass is used throughout the industry as a standard. Polypropylene, PVC, and similar thermoplastics are also used. Nitrates and urea products are typically handled by using type 304 stainless steel. Concentrated HNO_3 can attack FRP-type materials.

Lime Kiln and Similar Kiln Operations. Lime kilns are found in several applications, including the pulp and paper industry. Lime and other kilns produce hot gas that contains dust, most often requiring a pollution control system. When possible, a dry collection system is used, because it allows the material to be collected in a form that can be returned directly to the kiln. Some products are too reactive for this technique, or the temperature of the kiln is too high, so wet scrubbers are then used.

Most of the scrubbers on kilns are made of carbon steel. The problem of corrosion resistance is usually minimal, because the solutions tend to be alkaline or at least neutral. The primary problem is usually abrasion resistance. The basic collectors are manufactured of carbon steel, and high-wear areas are often made of stainless steel. Some units use heat treated stainless steel, which is hardened for the wear-resistant areas. Another technique is to install a liner to protect areas of greater wear.

Pulp and Paper Industry. Most of the pollution control problems in the pulp and paper industry consist of either the organic sulfur compounds produced from digesting the pulp or the chlorine-related oxidizing agents produced from bleaching the pulp. The reduced sulfur compounds are generally handled in FRP construction. Temperature limitations are not normally a factor, because most of these applications are at temperatures of 80 °C (175 °F) or less. Chlorine or chlorine dioxide applications are handled by materials discussed previously in this article. More information on materials of construction for the pulp and paper industry is available in articles about corrosion in the pulp and paper industry in this Volume.

Groundwater Treatment—Emission Control. Groundwater sources can become contaminated through tank leakage or buried waste. For example, chlorinated hydrocarbons traditionally used to remove grease and oil from aircraft engines for maintenance have been found in nearby wells. Levels exceeding the Environmental Protection Agency standard of between 1 and 5 ppb for most chlorinated organic compounds must be addressed. To remove these, groundwater is usually passed through either activated carbon or an aeration column called an air stripper.

The volatile organic compound easily evaporates into the air in the air stripper. If it is present in a very small quantity, regulations allow it to be discharged directly into the atmosphere, where ultraviolet light will break down the compound within 24 h. When it is present in a significant quantity, a second-stage treatment system, such as a vapor phase carbon system or thermal/catalytic oxidation, is used for destruction. If the contaminated water were sent directly to a carbon system, the adsorption of the compound may be 1 to 2 wt%. From air, 25 wt% is collected, so the air stripper increases efficiency.

While air strippers are exposed to chlorinated compounds and other reactive chemical species, the concentration of these components is extremely low. Stainless steel, polypropylene, or fiberglass have been found to be successful at these low levels. For small liquid flows, stainless steel is a common material of construction. Fiberglass is the most common structural material for the housing for larger liquid flows. For either the air-side vapor phase carbon or the liquid-side carbon, the most common material of construction is steel with an epoxy or similar finish. The combination of corrosion-resistant

lining and steel outer housing gives a good mechanical integrity at low initial cost.

Industrial wastewater treatment equipment, such as that treating the discharge from a scrubber, may require special materials, but the majority of groundwater treatment or industrial water treatment for emission control can be handled using epoxy-lined steel construction. Examples include settlers, flocculating tanks, retention tanks, and filtration equipment.

Metal fabrication plants may generate a combination of contaminants, because metal fabrication involves a very wide range of processes, products, and materials. It embraces any metal work that concerns itself with metal removal, forming, joining, and finishing, such as painting.

The treatment of bulk solids and the use of dust collectors were previously addressed.

Painting operations include spraying, dipping, and electrostatic finishing, among others. The coatings applied in these operations vary widely as to composition and physical properties. Where paint contains solvents, the volatile organic compounds released during the paint-drying process must be captured and treated. This usually requires the use of a thermal destruction system, such as a thermal, catalytic, or regenerative oxidizer (Fig. 5). For larger air flows, a regenerative thermal oxidizer is used. In this technology, the air is heated through a ceramic bed close to the operating temperature, at which point the gas is further heated with a direct flame to destroy the organic compounds. The exhaust gas then exits through a ceramic bed that captures its heat. The beds are alternated so that as the inlet bed cools, the gas switches direction and passes through the preheated former exhaust bed. Using this technology, a 90 to 95% thermal efficiency can be achieved.

Fig. 5 A catalytic oxidizer of stainless steel construction. Courtesy of Branch Environmental Corporation

The heat-transfer medium is virtually always a ceramic bed of either structured packing or random packing. The housing itself is typically carbon steel. It would be unusual to encounter any chlorides or sulfur compounds in painting facilities. The solvents are usually all organic, and the combustion products are typically carbon dioxide and water.

The face of the support structure for the ceramic is often made of heat-resistant stainless steel. As long as the housing is maintained at or above the temperature of the gas dewpoint, corrosion should not be a problem.

Wastewater—Odor Control. In handling municipal wastewater, the collection, separation, and biological treatment of solids can result in the formation of hydrogen sulfide (H_2S) or other organic sulfide compounds, including methyl mercaptan, methyl sulfide, and dimethyl disulfide. Especially during sludge dewatering, the released odors are usually captured in an air pollution control system consisting of one or more stages of counterflow packed tower absorbers. These absorption columns typically contain alkali solution and a bleach such as sodium hypochlorite to react with the compounds and effectively destroy them, with efficiencies over 99%.

While the air containing sulfide compounds will be somewhat corrosive, the scrubber solution containing sodium hypochlorite (bleach) is extremely aggressive and will attack most metal compounds. Fiberglass or other thermoplastics have found extensive use in wastewater plants for this reason (Fig. 6). The scrubber housing, recycle pump, and related components are typically made of fiberglass using vinyl-ester resins with synthetic veils. Where critical components

must be made of metal and exposed to the solution, Hastelloy C has been used. Because there is always the chance that sulfides are present externally, items such as hardware are usually made of type 316 stainless steel.

Textile Mills. Finely divided lint is present in quantity in the air in the vicinity of various operations associated with handling yarn and cloth. Most modern mills have air tunnels to capture this lint and carry it to a central collection point. A filter constructed of galvanized steel with flat flexible stainless steel screens to support the raw filter media is used.

In finishing operations, especially in textile drying, the knitting oils may be driven out of the fabric during heating. These can result in a smokelike emission that is either captured with a cooler/fiber bed mist eliminator or destroyed through thermal oxidation. While there are no special chemicals of concern involved, the thermal oxidizer uses type 304 stainless steel to eliminate corrosion problems from the high temperature. The cooler/filter approach uses stainless steel for the first-stage scrubber and an epoxy coating for the remainder of the system to avoid corrosion from the condensed water.

During manufacture of synthetic fibers, the process can generate a number of chemicals that must be controlled, using the same techniques employed by the chemical process industry.

One of the largest concerns with textile processing is the wastewater treatment. The recovery and reuse requires pH adjustment, suspended solids removal, and removal of color. These steps typically do not involve extremely corrosive chemicals and can be handled using lined or coated steel construction.

The food industry uses large quantities of water. The canning industry uses 190 L (50 gal) of water per case, for instance. Every effort is made to clean the water, either for reuse or to meet water-release regulations.

Water can contain suspended or dissolved solids. The typical control steps of screening, flocculation, or filtering as described for wastewater treatment are used, and the same materials apply.

Odor control for air handling is also of concern. While the odor from coffee would not be considered offensive in small quantities, a coffee-roasting operation typically takes steps to provide mechanical separation of dust from the roasting operation. It may employ a catalytic or thermal oxidizer on the discharge to eliminate further odors. Because the emissions for most food operations are primarily hydrocarbons, the material of construction for the typical catalytic oxidizer is type 304 stainless steel.

Corrosion in Recreational Environments

Lorrie A. Krebs, Anderson Materials Evaluation, Inc.
Michael LaPlante, Colt Defense LLC
Jim Langley, USA Cycling Certified Mechanic
Kenneth S. Kutska, Wheaton (IL) Playground District

THE RECREATION INDUSTRY is large and widespread, covering a huge number of sports, games, and activities that take place in environments as diverse as the activities themselves. Also huge is the amount of money spent in the United States alone just on merchandise related to recreational activities. The 1997 Economic Census in the area of Arts, Entertainment, and Recreation reported that Americans collectively spent more than \$3 billion on the rental or purchase of equipment and merchandise related to a selected series of activities that included golfing, skiing, racquet sports, and boating among others (Ref 1). Furthermore, this figure reflects only the receipts and revenues of facilities at which people can engage in their activities of choice (golf courses, ski resorts, etc.). The expenditure is significantly greater when one considers the many commercial vendors that supply sporting and recreational equipment without affiliation to a specific recreational facility. For example, a market analysis statement published by Tennis Master Pro Shops, Inc., in the mid-1990s reported overall sales of tennis-related equipment alone to be \$2.3 billion annually. According to the National Golf Foundation, golfers spent \$4.7 billion on equipment in 2002. These and similar dollar figures for any number of recreational sporting activities clearly indicate that the market for sporting and recreational equipment is a substantial one.

Materials requirements for the equipment needed to participate in these many activities are widely varied as well. As is the case in many industries, strength, size, and weight are often factors when selecting a particular material for a particular purpose. Materials selection for corrosion addresses issues ranging from demanding atmospheric and immersion environments (e.g., marine environments for recreational boating) to small-scale corrosion related to handheld materials that can react to perspiration (e.g., barrel exteriors of some firearms). Despite the wide range of shapes, sizes, and functions covered in this category, some commonalities in materials and material failures can be identified. Aluminum alloys, for example, are used extensively in recreational equipment for a variety of reasons

including strength combined with light weight and pleasing appearance. However, improper anodization can cause corrosion-related failures in a range of equipment. Separate incidences of incorrect aluminum anodization have been identified during failure analyses, including the discoloration of knitting needles by handling in one case and the collapse of a residential swimming pool ladder in another. The consequences of such failures range from merely inconvenient to physically harmful and possibly life threatening.

The move from metals to composites in some sports equipment, such as high-end tennis rackets and golf clubs, was motivated more by performance than by corrosion characteristics, although proper cleaning and maintenance will extend the life of metal handheld sports equipment. Other recreational areas are far more sensitive to corrosion issues. Several such activities are explored in this article from the point of view of corrosion in typical environments and the actions taken to improve corrosion performance. The subset of recreational equipment specifically addressed here includes recreational boats, firearms, bicycles, playground equipment, and climbing gear. Corrosive attack may stem from operation and handling of particular items and/or from environmental exposures. The methods chosen to mitigate corrosion while still addressing other functional issues for the given piece of equipment include base materials selection, surface treatments and coatings, and good practice of maintenance procedures.

Corrosion in Boats

There are few environments more conducive to corrosion than that experienced by and on a marine vessel. Boats are composite structures, consisting of a variety of dissimilar metals and other materials, all exposed or immersed to one degree or another in one of the most efficient electrolytes for corrosion, water, and most especially saltwater. Add to this the electrical and electronic systems of the boat, which can result in stray currents, and the potential for

corrosion problems increases even more. Metals on boats experience all forms of corrosion—general, pitting, crevice, atmospheric, galvanic, stray-current, fretting fatigue, erosion-corrosion, cavitation, stress corrosion cracking (SCC), and microbiologically influenced corrosion. Consult the next article “Corrosion in Workboats and Recreational Boats” in this Volume for more detailed information on boating corrosion issues. These include corrosion of:

- Hulls, fittings, and fastenings
- Metal deck gear
- Equipment such as winches, lifeline supports, and anchor systems
- Propulsion systems
- Electrical and electronic systems
- Plumbing systems
- Masts, spars, and rigging

Corrosion of Firearms

Corrosion has been the main enemy of firearms since their invention more than 500 years ago. It occurs both on the outside surface of the firearm as well as on the inside surfaces, particularly in the bore of the barrel.

Early Construction and Propellants

The most common form of corrosion in firearms is rust, simple iron oxides, created when chemical iron dissolves in aerated water. This can be caused by a large number of factors such as use in a humid environment or exposure to the elements (rain, snow, etc.). Some people have very acidic sweat and can cause damage merely by handling their firearms. Since none of these factors can be entirely eliminated, owners have always been required to wipe down the exterior surfaces of their firearms after every use to first remove moisture and then to wipe them down again with an oily rag to provide a moisture-proof barrier. More recently, silicone-impregnated cloths have become available to wipe down firearms after use, offering yet another barrier to moisture.

Far more destructive than external surface rust is corrosion in the barrel bore. For hundreds of years the only propellant available for use in firearms was black powder. The residue left after firing is so hygroscopic that corrosion begins almost immediately after firing. Owners were required to wash the barrels out with hot (and preferably soapy) water as soon as possible to prevent corrosion. Modern shooters using replica black powder firearms are still required to do this. Exhaust that emerges near the hammer at firing can also attack the barrel exterior locally, as shown on the replica black powder rifle in Fig. 1.

A little over 100 years ago, manufacturers began to switch to so-called smokeless powders that exhibit this characteristic to a lesser degree. The problem then became one of corrosion caused by chlorates in the priming compounds. After firing they turn into chlorides, which attract moisture. While washing with hot and soapy water would also work with these compounds, chemical cleaning solutions were developed to neutralize these chloride compounds. Even so, cleaning was required as soon as possible after use. Eventually, primers were developed that do not contain these chlorates. Today, in virtually all cases, commercial sporting ammunition is loaded with noncorrosive powders and primers.

Nearly all firearms were originally manufactured from iron, the only available material that was strong enough to contain the pressure of the burning propellant in the barrel. Iron was also used to provide the various other components such as hammers, triggers, and sears. Springs were usually made from steel. In the last half of the 19th century, alloy steel became the preferred material for all components, offering additional strength and allowing reduced weight. Obviously, corrosion was still a problem.

Changes in Construction Materials

Aluminum. In the last 50 years aluminum has been used for components where material

strength was less critical and reduced weight offered other advantages. "Rust" is not a problem with aluminum components, although hardcoat anodizing does provide some additional protection from oxidation.

Stainless steel first made a significant appearance in firearms in 1960. The main advantage of stainless, of course, was to reduce corrosion. Even though the materials chosen were usually 400 series stainless or various precipitation-hardening materials, they still provide much more protection against corrosion than alloy steel.

Polymers. In 1980 polymers made their appearance, in much the same way that aluminum had earlier. Polymers are often used for such components as handgun receivers where they serve as a base on which to assemble the more highly stressed components. Obviously, polymers do not corrode and have the added advantage that they can be molded in whatever color the manufacturer desires.

Surface Coatings and Treatments

Plating and Polymer Coatings. Firearms manufacturers realized from the beginning that additional corrosion resistance was required on both interior and exterior surfaces. At first they turned to treatments that were already available. These included plating the exterior surfaces with silver, nickel, and even gold. More recently, manufacturers have used chrome plating, both hard and soft, on the interior and exterior. This type of coating is especially useful in preventing corrosion in barrel bores. Currently, manufacturers are experimenting with advanced plasma vapor deposited coatings such as titanium carbonitride and polyvalent diamond compounds to reduce wear and improve corrosion resistance on both the interior and exterior. In addition, there are now a number of commercially available polymer coatings that users can apply to the exterior of their firearms by such means as painting or spraying. Many of these contain molybdenum disulfide, which acts

as a dry-film lubricant in addition to providing corrosion resistance.

Oxidation Treatments. Many early firearms were finished "bright," that is, polished and untreated. This obviously left tremendous opportunity for corrosion and was one of the reasons so much time was spent on keeping firearms clean. Eventually, browning and then bluing processes were developed to protect the interior and exterior surfaces. The processes are similar; both artificially rust the iron surface and leave a pleasing finish. In the first case a thin layer of ferrous hydroxide ($\text{Fe}(\text{OH})_2$) is formed on the surface, which gradually converts to brown ferric oxide (Fe_2O_3). The bluing process (originally using steam or boiling water) converted the brown ferric oxide to the much darker ferro-ferric oxide (Fe_3O_4).

Phosphate Treatments. After World War I, additional treatments were developed to provide greater rust protection than browning or bluing. Many of these involved treating the exterior surface with a solution of phosphoric acid and other ingredients, often including manganese phosphate. One of the most popular of these in the United States was the patented Parkerizing process, which utilized zinc phosphate.

Treatments for Stainless Steels. With the use of stainless steels, manufacturers followed two schools of thought. Some manufacturers relied solely on the corrosion resistance of the stainless steel and provided no additional finishing after polishing. Others took the additional step to passivate the components after polishing to remove the free iron particles on the surface and further reduce the possibility of corrosion. The jury is still out as to which approach is superior.

Case Hardening. Some early components such as hammers and triggers were case hardened. This not only increased their hardness and wear resistance, but also provided some corrosion resistance. Only recently have firearms manufacturers gone back to this seemingly simple form of surface treatment, using the Mellonite and Tenifer molten salt processes.

Fig. 1 The red dust shown from two views on the dark barrel exterior of this black powder replica rifle was the result of residue in the exhaust and implies that far worse corrosion is probably present on the interior surface. Courtesy of Daniel Sullivan

Bicycles and Corrosion

In the 138 years that bicycles have existed, the vast majority have been built of alloy steel. While more and more models designed for the enthusiast market of today (2006) feature nearly corrosion-free materials such as aluminum, carbon fiber, composites, and titanium, steel remains the most-used material worldwide because it is affordable, easy to work with, durable and because it makes “nice-riding” bicycles. Consequently, this section focuses primarily on corrosion issues with steel bicycle frames and components because these parts are the most at risk for corrosion and also because there is more historical information regarding their performance. For example, while aluminum was used for bicycle frames as early as 1902, it did not become popular until Cannondale introduced its first bicycles in 1984. Carbon fiber, titanium, and composite bicycles (blends of carbon and aluminum or titanium) have even less history to draw on (Fig. 2). Yet, what is known so far is that they are so much more resistant to corrosion than steel that serious degradation problems are basically unknown.

Unless fastidiously maintained and carefully kept, most steel bicycles succumb to corrosion in one way or another, sooner or later. In time, corrosive attacks occur even on painted and plated steel and can ruin everything from the frame and fork to the drivetrain, wheels, and bearings if ignored. Selected examples are discussed below.

Frames and Forks

Frame and Fork Corrosion. Bicycle frames comprise welded tubular steel of various qualities from high-tensile strength steels to

chromium-molybdenum alloys. Weight is always an issue when designing and building bicycle frames. As a result frame tubing is usually as thin as possible, taking into consideration the performance goals of the machine and associated cost. In some cases, the tube wall thickness can be as little as 0.4 mm (0.016 in.). Obviously it does not take much corrosion to weaken tubes this thin.

Manufacturers always protect the steel frame and steel fork exterior surfaces with paint and/or plating, which is adequate for preventing corrosion in most cases. Problems arise when the paint or plating gets chipped, scratched, or worn away, exposing bare metal to a potentially corrosive environment. Corrosion beneath the paint (undercutting) is also possible if the frame was not correctly prepared before painting. If left unchecked, the rust that forms on an exposed surface or beneath the paint will eventually lead to loss of wall thickness and perforation of the tubes, potentially ruining the frame.

Also of concern are the interior surfaces of the tubular frames and forks, which are not painted and are susceptible to rusting once moisture enters the frame. Moisture inside the frame and fork can build up over time due to condensation. Moisture ingress can also occur by seepage past the seatpost from water spray off the back wheel on rainy rides. While most quality frames include venting holes that help some of this moisture evaporate, rust can form any time moisture finds its way into the frame. If left unchecked, as is usually the case, it will eventually weaken the frame by loss of wall thickness and/or by perforation.

The interior surfaces of the tubular steel used for frames and forks can be protected by plating. However, improper plating can cause rapid corrosion of the inside of the frame. This is rarely a concern with production bicycles built by major

manufacturers who understand the challenges of proper plating and take precautions to protect the tubing. However, less-established and unprofessional builders occasionally cut corners in the plating process. This also happens when owners, who are repainting their bikes, have them plated by companies that are not experienced with thin-wall tubing. Poor plating practices leave chemicals inside the frame tubing that can actually accelerate the corrosion process. Because this attack takes place hidden from view inside the tubes, a frame can often rust quickly and fail in just a matter of years.

Preventative Measures for Frames and Forks. It is possible to prevent most rusting problems simply by limiting exposure. Avoiding inclement weather whenever possible, cleaning and lubricating the machine immediately after wet rides, and storing the bicycle indoors are all excellent ways to limit moisture ingress to the interior as well as exposure of the exterior surfaces. Another measure that will protect frames and ensure long life is to apply wax. Wax coatings add a protective layer on top of the paint and help to seal any small chips and scratches. Wax coatings are also soft and wear easily, so they should be reapplied roughly every 6 months. It is always best to immediately touch up any chips in the paint and to sand any rust spots to bare metal, refinishing the area appropriately to protect the steel as soon as any problems appear.

Another excellent practice is to protect the inside surfaces of the frame with a rust preventative. Silicone sprays, such as WD-40, can be sprayed through the vent holes and down the tubes. Then by rotating the frame, the liquid can be spread to coat and protect the tubing. An alternative is linseed oil, which dries to form a harder protective coating. There are additional products available through bicycle retailers that are easy to use and very effective.

Corrosion caused by shoddy plating is the result of chemical residue left in the frame during the plating process. This residue accelerates the corrosion process, especially with the ingress of moisture. This is something the plater needs to understand and correct. To prevent this problem it is necessary to bake the frame in an oven at a low temperature (175 °C, or 350 °F) to eliminate the chemicals and protect the tubing. Typically, only experienced professionals perform this step.

Other Components

Component Corrosion. Even on inexpensive bicycles many corrosion-free anodized-aluminum parts are used. However, many of these components include steel subparts, such as axles, nuts, and bolts. There are also many important components, such as chains, cassette cogs, chainrings, spokes, pedals, and derailleurs in which steel is commonly used due to strength requirements. If these steel components are not lubricated regularly, corrosion will quickly cause problems, such as frozen chain links that prevent smooth pedaling and shifting, binding brakes

Fig. 2 This Cannondale composite bicycle has an aluminum frame and a carbon fiber fork, resulting in a more corrosion-resistant bicycle than the more common (worldwide) steel frames. However, important components such as chains, axles, and bearings are still commonly made of steel for strength requirements and must be maintained to prevent corrosion from forming and interfering with performance. Courtesy of Greg Welsh

that will not release or grip, shifting and braking glitches from rusted cables, and bearing damage in the wheels, drivetrain, and steering systems.

These types of corrosion-related failures are all common results of water entering steel components. For instance: water follows exposed cables into the housing, cannot escape, and corrodes the cables, binding them and possibly freezing them inside the housing. Water seeps past seals and gets inside the wheel, steering, and crank bearings where it rusts the balls and races, causing them to grind to dust over time. Water can also enter the chain links freezing the sideplates and rollers, making smooth pedaling and shifting impossible. Corrosion can also cause problems with wheels where it can freeze the nipples to the spokes making it impossible to straighten the wheel should it go out of round or true. If the wheels develop wobbles that cannot be straightened, the braking system is also compromised.

Rubber, nylon, and plastic materials on bicycles, such as tires, brake pads, and seats degrade, too. This is likely if the bicycle is stored outside and exposed to rain, air pollution, and the rays of the sun. It is also caused by riding hard or frequently in bad weather. However, even when carefully cared for, tire sidewalls rot due to the effects of the sun and air, rubber brake pads harden and lose their grip, and synthetic seats may turn brittle and crack.

Another incidence of corrosion that plagues bikes ridden regularly in all weather conditions is certain components freezing in the frame, such as the seatpost and handlebar stem. Sometimes, the materials themselves cause this to occur. For example, the typical setup of a steel frame with an aluminum seatpost has the potential over time of creating electrolysis between the two parts, causing them to almost become one piece and making them immovable (except by a knowledgeable professional mechanic and even then not easily). Even when the materials are the same (steel frame/steel seatpost), they can freeze if corrosion has occurred in the crevice between them.

Preventative Measures for Components.

Fortunately, most component corrosion (including frozen components) can be prevented with regular lubrication and maintenance. Components that cannot be protected this way (e.g., tires, brake pads, and seats) can be affordably replaced as needed. By following the industry recommendation of getting a tune-up every six months and a bearing overhaul yearly, cyclists typically will not experience significant component problems due to corrosion. This practice should be coupled with basic home maintenance such as routinely lubricating the chain, derailleur, and brakes to keep a protective coating on most of the corrosion-susceptible parts. It is also possible on many modern bikes to lubricate the cables without tools and without changing any adjustments. If done every six months, the shifting and braking will work optimally and the cables will last almost indefinitely. Another modern trend that is

helping to prevent corrosion and related problems is the use of nylon bushings where metal washers were once used, such as in the brakes and derailleurs. These offer a type of nearly maintenance-free permanent lubrication and reduce corrosion-related problems significantly.

Similarly, to prevent corrosion in the wheels, manufacturers are beginning to use stainless steel spokes. If the spoke threads were lubricated during wheel assembly it would prevent the frozen nipples that cause wheel-truing problems. Unfortunately, this is not the common practice unless the cyclists know enough to lubricate the threads occasionally on their own.

Bearing components rely on grease for corrosion prevention. The hubs, crankset, and headset are more challenging to maintain because they are inaccessible without special tools and know-how and because they are not readily apparent and as a result are easily forgotten. As with spoke thread problems, many bearing problems would be solved if manufacturers would, during assembly, simply install more grease in their components. All new bicycles sold by independent bicycle dealers must be assembled before sale, and mechanics often discover underlubricated bearings at that time. Adding lubricant ensures longer life for the bicycle. However, many more bicycles are sold through chain and department stores where such attention and care are rare. Consequently, for bicycles that are ridden regularly or hard or are stored outside, there is usually insufficient grease inside the all-important bearing systems to protect the components for long. This often leads to corrosion, failure, and an expensive repair. For example, if the rear hub bearings and races are damaged by rust, the entire wheel will need to be replaced, an example of a significant expense that could be avoided by proper lubrication at the outset. Generally, all components of a bicycle can be kept free from corrosion and running smoothly with proper lubrication and good general maintenance.

Public Playground Equipment

Metal corrosion is one of many safety concerns with no simple answer regarding public playground equipment. Public leisure industry managers of today (2006) continue to promote and defend their capital replacement, repair, and maintenance budgets, but many times these funding requests are unsuccessful, leaving repair and replacement programs unfunded or filed away in a place called "deferred maintenance." How long can these issues be deferred before they become a real safety issue? There is no definitive answer to this question. Observations throughout the world have shown that there are many public agencies that fail to properly maintain their property. This inaction may be due to a lack of funding, but most often it is due to the lack of knowledge and experience necessary to address the situation before it becomes a serious problem.

The playground equipment industry has grown rapidly over the past 20 years. Once comprising postwar manufacturing companies building one-of-a-kind metal climbers, swings, slides, and other outdoor gymnasium equipment, the industry has evolved dramatically with the development of more sophisticated manufacturing techniques and a wide range of materials. There seems to be no end in sight with regard to the purchasers' ability to design their own elaborate composite play structures utilizing custom computer drafting programs that can, with a touch of the keyboard, add or delete a multitude of play components. Each component may be made in a variety of materials and in almost any color, giving the designer the ability to meet their specific aesthetic needs.

The evolution of playground equipment manufacturing has resulted in the acquisition of many well-known names within the industry by large national and international conglomerates with sales in the billions of dollars. This industry was left unchecked until 1981 when the Consumer Product Safety Commission (CPSC) issued its first federal guideline as a two-part handbook for public playground safety. In 1991, CPSC revised its handbook after conducting an injury analysis using the National Electronic Injury Surveillance System (NEISS) to determine who was being injured on public playgrounds, as well as the type and cause of the injury. In 1990, according to the CPSC, more than 150,000 victims were treated in U.S. hospital emergency rooms for injuries associated with public playground equipment. In 2000, that number had increased to more than 200,000. Some of these injuries, and even deaths, occurred as a result of component and fastener failures. Such failures are often associated with corrosion of a structural member and/or of the fasteners used to support and connect structural or load-bearing components. The ever-increasing number of playground injuries raises serious concerns. While there is no current federal law mandating a standard of care for public playgrounds, there is a voluntary industry consensus-based standard for public playgrounds developed and revised over the past 15 years through the American Society for Testing and Materials (ASTM). ASTM and CPSC along with many other national organizations are continuing to look for answers that will minimize permanently debilitating injuries sustained by children on public playgrounds.

More than 30 years ago, playgrounds were thought to last indefinitely. At that time, manufacturers lacked detailed installation instructions and maintenance instructions were almost nonexistent. Just add a coat of paint and everything would be as good as new. Most equipment was fabricated from steel pipe, and longevity was never considered an issue within the marketplace. Durability of products used in public playgrounds has, until recently, been an unanswered question since no equipment life expectancy was specified at the time of purchase. The marketplace of today (2006) is more

sophisticated and still evolving. New designs are made possible by new materials not conventionally used in manufacturing public playground equipment. These rapidly changing innovations in play equipment design, while allowing the creation of ever more imaginative play spaces, make it impossible to forecast a replacement date before a component or fastener fails.

There appears to be no end in sight for the future designs of play equipment with the recent introduction of many other metals, composites, and plastics. With these new materials come problems related to compatibility of adjacent components and fasteners. ASTM F 1487, "Standard Consumer Safety Performance Specification for Playground Equipment for Public Use," section 4, states that playground equipment shall be manufactured and constructed only of materials that have demonstrated durability in the playground or similar outdoor setting (Ref 2). Metals subject to structural degradation such as rust shall be painted, galvanized, or otherwise treated. Woods shall be naturally rot- and insect-resistant or treated to avoid such deterioration. Plastics and other materials that experience ultraviolet (UV) degradation shall be protected against UV light. Regardless of the material or the treatment process, the user of the playground equipment cannot ingest, inhale, or absorb any potentially hazardous amounts of substances through body surfaces as a result of contact with the equipment. Couple these requirements with the need to provide nontoxic environments suitable for people, especially children who are more chemically sensitive, one can see the necessity for a complete, coordinated planning effort throughout all supply lines within the playground industry.

According to the National Recreation and Park Association's (NRPA) National Playground Safety Institute (NPSI) certification program for public playground safety inspectors, one of every three playground injuries is alleged to be caused by improper, or a complete lack of, facility maintenance. As a result of the heightened public awareness of these issues, many agencies have begun to do their part to help reduce preventable injuries by conducting routine inspections, maintenance, and repair of their playgrounds. A thorough facility inspection coupled with timely corrective action by the inspector once a defective or degraded component is identified is the only sure way to eliminate a safety problem before it occurs.

Types of Corrosion Encountered in Public Playground Equipment

Adverse conditions found on playgrounds include prolonged contact with water, contact with excessively high or low soil pH, acid rain, high humidity, salt air, various organisms commonly found in dirt, and human and animal excretions. In addition to water with dissolved ionic components, excretions can corrode metal

or can produce waste products that can react with and corrode metal. Therefore, regular cleaning of play equipment not only keeps it attractive and sanitized but also deters corrosion.

Some metals naturally corrode more slowly than others, thereby extending the life and play value of the equipment. The only guidance given through the ASTM F 1487 standard is the reference to ASTM F 1077, "Standard Guide for Selection of Committee F-16 Fastener Specifications" (Ref 3). In addition to ASTM F 1487, there are several other ASTM standards that specify the previously mentioned rather vague compliance standards for materials used throughout the playground equipment industry. These include ASTM F 1148, a standard for home play equipment (Ref 4), ASTM F 1918, a standard for soft-contained play systems (Ref 5), and a soon to be published ASTM standard for public-use play equipment for children 6 to 24 months. These standards require demonstrated durability and state that materials must be corrosion resistant. They do not, however, specify how structural metals are to be protected with barrier coatings that keep the moisture and air away from the metal. Protective, corrosion-resistant coatings typically used on playground equipment components include metal plating, galvanizing, powder coating, liquid vinyl coating, and paints.

The most common form of metal deterioration on the typical public playground is the corrosion of steel, generally referred to as "rust." Any structural metal will corrode over time, however, and without mitigation the structure weakens, deteriorates, and eventually disintegrates as shown in Fig. 3. Corrosion attack can vary, depending on the geographic region. Knowledge of the common everyday environmental factors within regions (e.g., temperature, humidity, rainfall, etc.) can help a planner to make an informed purchasing decision when specifying the type of materials and hardware to be used. Unfortunately, most public officials responsible for the procurement of public play equipment are not well versed in the cause and effect of metal corrosion, the impacts of various environmental factors, or the potential issues associated with adjacent dissimilar materials.

When a component shows signs of failure, it should be replaced with the same component as provided by the original manufacturer unless otherwise authorized by the manufacturer. This replacement needs to take place before the damage becomes serious. Oftentimes, however, when a problem is identified the solution is to run to the local hardware store, lumber yard, or maintenance facility and grab the first thing that appears to fit the need, unaware that this action may cause a much bigger problem. The average person knows little about metal corrosion other than what is referred to as common surface rust resulting from the loss of the protective coating and exposure of the steel to moisture. When these protective coatings are worn away or scratched off during normal use, the unprotected metal underneath is exposed and surface rust begins to

form. In its initial stage it is relatively harmless. However, it is good preventive maintenance to routinely inspect all coated metal components to find and repair exposed metal where surface rust is starting before it becomes a larger problem. Removing loose rust with steel wool or a wire brush and applying a rust-neutralizing solution evenly over the affected area followed by an application of the appropriate primer and topcoat recommended by the equipment manufacturer would be the first line of defense before rusting becomes a serious problem as depicted in Fig. 4. The individual equipment manufacturer should always be contacted for proper inspection methods and corrective procedures.

There is a wide variety of types of corrosion that can be found in playground equipment resulting from both man-made and naturally occurring conditions. The forms of corrosion can

(a)

(b)

Fig. 3 Examples of playground and equipment corrosion. (a) When debris and moisture become trapped on surfaces for long periods of time due to lack of maintenance, improper design, or improper installation, corrosion can affect the function and safety of the play component. (b) All materials will corrode over a long period of time, as demonstrated by this stainless steel slide bedway. Courtesy of the NRPA NPSI

include weld decay (Fig. 5), crevice corrosion, pitting or exfoliation, fretting corrosion, under-deposit corrosion, galvanic attack (Fig. 6), white rust corrosion of a galvanized surface (Fig. 7), and soil and/or microbiologically influenced corrosion (Fig. 8). Manufacturers, designers, and engineers working together with an informed and educated marketplace can make great strides in mitigating the inevitable corrosion of playground components by selecting the proper compatible materials for the intended installation environment. Regardless of the type of corrosion, however, taking the necessary precautions of timely inspection, maintenance, and repair of the play equipment can alleviate and/or eliminate corrosive attack. Every owner/operator can maintain and prolong function and play value by keeping their equipment free of foreign substances and by treating rust when it first appears by cleaning, treating, or replacing hardware showing evidence of corrosion and/or by properly cleaning and coating or otherwise encapsulating structural components with appropriate materials.

Unfortunately for older playgrounds, many pieces of play equipment damaged by corrosion have been discontinued or parts are no longer available. When this occurs, the professional judgment, knowledge, and experience of the owner/operator will be challenged to determine

the appropriate corrective action. To address this issue, the Park District Risk Management Agency (PDRMA) prepared a comprehensive maintenance training program. These training materials elaborate on all forms of corrosion commonly found in playgrounds of today (2006) (Fig. 7, 8). Detailed explanations of the type and cause of the different forms of corrosion along with instructions on the procedures and materials required to correct each situation are included. Owner/operators can improve conditions by becoming aware of the factors impacting metal corrosion in order to make informed decisions when purchasing, installing, maintaining, and inspecting public play equipment. Understanding the environmental characteristics of a given region, the expected reactions between materials used in fabrication of play equipment, and the appropriate use of corrosion-resistant material or protective coatings that can extend the life expectancy of a product are just a few of the areas addressed. Another factor accelerating the loss of corrosion protective coatings on playground equipment is the amount of use the equipment receives day in and day out. It is critical to understand all aspects of the local playground environment to better maintain and extend the life of a piece of equipment while

ultimately reducing the frequency and severity of playground-related injuries.

Free Rock Climbing

The sport of climbing takes many forms, largely dictated by the locale and the desired activity of the climber. These forms include mountain climbing or mountaineering, ice climbing, bouldering, indoor climbing as in a "rock gym," aided rock climbing, and free rock climbing. While there are some commonalities between the equipment used and environments encountered in the outdoor sports of aided and free rock climbing, the focus of this section is on free climbing.

Safety Equipment

While aided ascents require the active use of equipment to make progress along a rock face, free climbing can be done with or without equipment. When equipment is used, it is there to catch a climber in the event of a fall, not to assist in the ascent. The act of using a safety system operated by a climbing partner to catch a falling lead climber is known as belaying. Important metal components of any belay system include carabiners and items that fall under the category of "protection" and include pitons, bolts, chocks and nuts, friends, and variations of these. Some items are carried by the leader. They are placed along the route for the protection of the leader during the initial ascent until an anchor is established at the end of a pitch. The belayer then collects the pieces as he/she ascends after the leader. After a careful inspection and cleaning those pieces may be used again on another pitch or climb. Other items are placed and left permanently in the rock face for the use of other climbers who will follow the route at later times. "Permanently" is usually defined as "until it breaks or shows signs of imminent failure." It should be noted that the loading of any of these items can be gradual and relatively static during

Fig. 4 Once protective coatings have been removed from playground equipment, corrosion occurs rather rapidly, accelerated by dirt, moisture, and other environmental factors including human contact. Courtesy of the NRPA NPSI

the course of a climb, for example an anchor for a hanging belayer, or it can happen suddenly in the event of a fall of the leader. Longer falls clearly have the capacity to increase the dynamic loading considerably. All of the safety equipment must be capable not only of providing support to static loads, but also of surviving the shock of a fall. The materials used in these devices consist of a variety of alloys, some of which have changed over the years as the sport has progressed. Some of the history and issues pertaining to carabiners and protection are summarized below.

Carabiners are the links between a climber and the rope, the rope and the protection equipment, the rope and a belay anchor, and so forth. Originally fabricated from steel, some pre-WWII European carabiners could bear static loads of no more than 270 kg (600 lb). An increase in weight in the carabiner body improved the load capabilities, but a change in alloy and design undertaken by American manufacturers resulted in far more significant performance gains. The change in design and the use first of 4130 steel (G41300) and then of heat treatable aluminum-copper alloy 24 ST occurred during WWII for the benefit of the American military's Mountain Troops. These improvements ultimately benefited the general climbing community as well (Ref 6).

Today (2006) carabiner bodies are fabricated predominantly from 7xxx-series aluminum alloy bar stock, chosen for their light weight and strength. At least one manufacturer specifies aluminum alloy 7050-T6 (A97075) for their carabiner bodies. The hinge pins may be composed of other alloys. Depending on the length and difficulty of a climb, a leader may carry dozens of carabiners at the outset; consequently, weight continues to be a very important factor. Additional weight can be shaved by reducing the cross section of a carabiner (Fig. 9), but this of course also reduces its rating in terms of the load it can support.

Pitons simply are flat or angled metal blades that can be inserted into a crack in a rock face. The size, style, length, and thickness of the plate can vary greatly, and a wide assortment was necessary in order for a leader to match a piton to the cracks encountered along a route. In the earliest days of the sport, iron pitons were fashioned by local blacksmiths and as a result exhibited dramatic variations in performance, some being too soft to drive reliably into a crack, others being too brittle and suffering fracture at impact. Around the time of WWII, metallurgical studies and advances in design led to the decision to use SAE 1010 low-carbon steel (G10100) with suitable heat treatments, providing a more consistent and reliable product that could be reused provided it could be removed from a crack (Ref 7). Alloy steels have also been introduced in the manufacture of standard pitons providing improved strength and stiffness with little compromise on ductility. Higher production costs for these pitons led to a more expensive final product, and softer steel pitons were still preferred

for some time. However, in the case of the very thin and flat "knife blade" pitons, chromium-molybdenum alloy steels such as SAE 4130 (G41300) were essential to meet strength requirements (Ref 8).

By the late 1960s removable protection, such as nuts and chocks, began to replace the piton in some climbing venues (Ref 9). These devices, usually quite simple in design and function, are typically made of aluminum alloys, often anodized, and sometimes combined with stranded steel wire to provide a stiff and strong attachment point for a carabiner. In these cases, the wire is galvanized to protect the strands from corrosion, which could reduce the cross section of the individual strands relatively quickly and severely compromise the usefulness of the protection in the event of a fall. The ease of placement and retrieval during climbing as well as the reduced damage to the rock surface itself helped to popularize this type of protection in many climbing communities. The variety and complexity of available retrievable protection hardware is quite extensive today.

Bolts are placed in a rock face by drilling a suitable opening in the rock. Consequently, a drill, drill bits, and bolts must be carried by the leader for placement during a climb. Some bolts are fully retrievable, while others have collars that are placed in the rock and allow the bolt to be screwed in and out. Still others are placed permanently as complete units. Once a suitable hole is available, the bolt maintains its position either by an expansion mechanism or by gluing. When anchor glue is used, it is squeezed into the hole first. The bolt is then slowly inserted and twisted to maximize coverage and to disrupt and remove trapped air bubbles. The bolt has an exposed threaded end with a nut, to which a variety of hangers can be attached as needed. When tight-

ened, the bolt shaft is kept in tension and the hanger stresses are dependent on the shape of the rock face against which it is pressed. Bolts and nuts are commonly stainless steel, although at least one manufacturer markets mild steel bolts with a thin stainless steel cladding. While stainless steel, and even stainless-steel-clad bolts, may be acceptable in many environments, corrosion issues in some geographic locations have forced recent innovations in materials selection for permanently placed bolts.

Environmental Corrosion Issues

Since most modern protection hardware is retrievable, corrosion issues usually center on maintenance. When gear is used outdoors, particularly in damp or humid locations, and most especially in coastal and tropical locations, proper cleaning is important. Removal of debris, rinsing with fresh water, and allowing pieces to dry is often sufficient to prevent corrosion of retrieved protection and carabiners used in coastal tropical environments as well as less severely corrosive environments. The more serious conditions occur when considering whether or not to rely on permanently placed equipment during the course of a difficult climb.

Equipment that is left behind intentionally or unintentionally should always be approached with caution. "Found" equipment, such as the carabiner shown in Fig. 10, should never be relied upon, even without the dramatically poor appearance of this particular piece. Even if the piece had been cleaned, the poor condition of the hinge and catch pins suggests that it may fail during a fall.

Pitons and bolts that have been left behind as permanently placed protection are another story. While these pieces are intended for the use of later climbers, it would be unwise to assume soundness without inspection. Inspection for a climber typically involves visually inspecting the part for corrosion or other damage, testing it for looseness as appropriate, and finally tapping it with a piton hammer. Motion during tapping would be undesirable, but climbers also listen for

Fig. 9 One way to reduce weight when climbing is to use carabiners with smaller cross sections. The trade-off is in the load-bearing capacity rating. Courtesy of Lorrie Krebs, Anderson Materials Evaluation, Inc.

Fig. 10 The carabiner in the foreground was found in a damp cave in upstate New York. A similar aluminum alloy carabiner is shown for comparison. In addition to white corrosion product generally present over all surfaces, there is red rust at the hinge and catch pins and the carabiner is frozen in the closed position. Courtesy of Lorrie Krebs, Anderson Materials Evaluation, Inc.

a distinctive ringing sound that indicates a piece was well set in hard rock. Many steel pitons of the older variety rust badly in almost any environment prone to regular rain and/or condensing humidity throughout the year because they have little in the way of natural corrosion resistance. Chromium-molybdenum steel pitons can be expected to fare better in similar conditions due to the corrosion resistance afforded by the chromium. Badly rusted pitons can fail in a variety of ways ranging from loosening inside the crack to breaking under impact and should always be avoided.

While rusty pitons have probably been a part of rock climbing for almost as long as pitons have been in use, a corrosion phenomenon relatively new to this sport has become apparent in more recent years. The relatively new popularity of sea-cliff climbing in warm tropical locations such as Sardinia, Thailand, and the Caribbean island of Cayman Brac has revealed a new hazard as documented in part at the website of the American Safe Climbing Association (ASCA, www.safeclimbing.org). Climbers visiting these locations are finding that stainless steel bolts have been fracturing under impact—either the impact of a piton hammer tap or, more seriously, the impact of an actual fall—in as little as 18 months after placement. The cause is chloride-induced SCC. Saltwater present as a spray or mist travels readily in the air, condenses on rock faces, and wicks into the crevice between the hanger and the rock where it attacks the bolt. Failure reports provided by many climbers indicate the bolts typically break in the shaft at the rock face as a result of an impact, large or small, with little or no visual evidence of corrosion observed prior to the break. The stainless steel hangers associated with these bolts typically have a 90° bend at which they are most likely to fail. The stainless steel nuts fitted to the threaded bolts also suffer SCC. In addition, four aluminum alloy carabiners retrieved from rock

walls in Cayman Brac after exposures of roughly 6 to 18 months overhanging the ocean were tensile tested to failure. While all four broke near or above their rated strength, the test revealed that the one exposed for 18 months failed due to SCC.

The solution for the bolt problem is a change both in material and in design. New bolts have been developed using titanium to replace stainless steel. These bolts are formed in the shape of a “P,” providing both a shaft to be anchored in the rock face and a loop to which a carabiner can be directly attached without threaded parts and associated crevices. The titanium is expected to have a far better survival rate in the aggressive coastal environment, but to add further protection the bolts are placed in the rock face with anchor glue. The adhesive, typically an epoxy, not only securely attaches the bolt to the rock, but also provides a barrier to moisture for the bolt shaft inside the hole. While the cost is substantially greater per bolt, the expected savings in averted injuries and equipment replacements makes the change worthwhile for these climbing sites. Other areas that may benefit from the new bolts are climbing and caving sites in wet areas with rock materials such as limestone, which may have leachable compounds that can dissolve and attack protection hardware. Aluminum alloy carabiners should be cleaned after use to remove potential corrosives. If one is found with a permanent anchor in a tropical coastal location it would be wise to be cautious about its use.

A Swiss-based organization known as the International Mountaineering and Climbing Federation (UIAA—Union Internationale des Associations d’Alpinisme) provides standards for strength requirements of climbing gear that are recognized worldwide. The ASCA reports that a special subcommittee within the UIAA has been formed to investigate marine environment bolt standards and to introduce their first standards specifically addressing corrosion issues.

Corrosion in Workboats and Recreational Boats

Everett E. Collier, Consultant

A MARINE VESSEL encounters an environment conducive to corrosion in all its forms: atmospheric, aqueous, galvanic, and micro-biologically induced. Boats are composite structures, consisting of a variety of dissimilar metals and other materials, all exposed or immersed in one of the most efficient of electrolytes, water, especially saltwater. Corrosion may be enhanced by stray currents from ship-board electrical and electronic systems. This article focuses on the corrosion and deterioration of components on recreational and small workboats; materials selection and corrosion control also are discussed. An extensive and thorough discussion of the use and protection of both metallic and nonmetallic materials on marine vessels is given in Ref 1.

Hulls, Fittings, and Fastenings

Fasteners and fittings must be compatible with the common marine vessel hull structures of wood, fiberglass composite, steel, aluminum, ferrocement, and sheathed hulls.

Wood Hull Fastenings. Silicon bronze and type 316 stainless steel are preferred above the waterline. Type 304 stainless steel, galvanized steel, and inhibited low-zinc (<15% Zn) brasses are acceptable. Mild steel, the free-machining grades (types 303, 303Se), and the 400-series stainless steels should not be used. Moreover, where the wood may become saturated, such as in hull planking, stainless steel fastenings should not be used. Conditions at or below the waterline (splash zone) are considerably more hostile than they are topside. Constant immersion in seawater or in seawater-saturated wood, or both, is highly conducive to crevice corrosion. These fastenings get no protection from cathodic protection systems such as zinc anodes, so their functional life depends on the corrosion resistance of the material or its protective coating.

Some of the newer superalloys, such as the 6% Mo stainless steels and Ni-Cr-Mo alloys, do much better and are finding increased use under these conditions, but they are expensive. Silicon

bronze is preferred, and galvanized steel is still being used.

Galvanized bolts and drifts are commonly found in the most demanding of the below-the-waterline applications: bilge fastenings, floor bolts, and keel bolts. The most corrosive damage occurs at the joint between the members: between the exterior ballast and the keel, between the keel and the floor timbers, between the floor timbers and the frame, and between planking and frames. Corrosion is accelerated in these areas, and the fastenings become wasp-waisted (Fig. 1). Threads should not be exposed in these areas.

The selection, installation, and maintenance of the keel bolt material should be done with consideration of the critical role of these fastenings and the difficulties involved in replacing them. A variety of keel bolt materials are used with cast iron ballast keels. Mild steel is the least expensive and is galvanically compatible with the iron keel; however, it is the most susceptible to accelerated corrosion in the joint area. Hot dip galvanized steel is advised. Type 316 stainless steel is also used, but it is essential to use sealants under the washers at the bolt ends and at the joint to prevent seawater penetration. Silicon bronze, aluminum bronze, nickel-aluminum bronze, and Monel are used, but these alloys are not galvanically compatible with the ballast iron and should be electrically insulated from it. Silicon bronze, aluminum bronze, nickel-aluminum bronze, and Monel are recommended with a lead ballast.

Organic coatings, even on the plank fastenings, are beneficial. A traditional coating choice for wooden hull fastenings is thick or thickened red lead. Some of the newer epoxy-based coatings also work well.

Wood Hull Through-Hull Fittings. On the outside of the hull, through-hull fittings are constantly immersed in seawater. On the inside, they may be immersed intermittently. In the hull, they are exposed to seawater-saturated, oxygen-depleted wood. A combination of corrosion resistance and mechanical strength is needed that exceeds most mild steel and common brass.

Most of the copper alloy seavalves, seacocks, or through-hulls and other underwater fittings are made of cast phosphor bronze (UNS C94300) or a cast leaded tin bronze, which is a highly corrosion-resistant alloy with a minimum yield strength of 90 MPa (13 ksi). This type of bronze corrodes extremely slowly in seawater and wet wood and does not need additional corrosion protection. Providing these parts cathodic protection may supply excess electrons, which would result in the overproduction of hydroxyl ions, the formation of sodium hydroxide in the saltwater-saturated wood around the fitting, and lead to delignification of the wood. Over-protection is generally not a problem where water flows freely over the surface of the fitting, preventing concentration of the caustic alkali (Ref 2).

Composite Hulls. Initially, fiberglass boats were hand lay-up and spray-up boats with successive layers of mat or woven fabric individually applied and impregnated with a liquid resin. In the search for greater strength-to-weight ratios and stiffness, other types of reinforcing fibers, such as other glasses, graphite, and aramid (Kevlar) fibers, and sandwich hulls came into use.

Fig. 1 Fasteners that appear solid at the ends may have hidden corrosion damage, such as the wasp-waisting of bilge fastenings.

Fastenings in Fiberglass. The fastenings most commonly used in fiberglass-reinforced plastic construction are bolts, self-tapping screws, and blind (pop) rivets. Silicon bronze is preferred over galvanized steel; stainless steels should be not used where oxygen is unavailable. There are some situations that are peculiar to fiberglass hulls.

Hard metal fastenings impose high local loads on the relatively thin, brittle laminates, so these loads must be spread through the use of well-bedded wood backing blocks and large (two to three times the bolt diameter) washers. Cathodic overprotection of metal fittings and alkali delignification of the damp backing wood is a potential problem.

Through-bolts are preferable where they can be used. Keep in mind that moisture trapped in the screw hole against the screw can cause crevice corrosion in stainless steel fastenings, and a sealant should be used. Blind rivets are used for deck-to-hull joints and for some small hardware where the backside is inaccessible. Closed-end types (to prevent moisture penetration), in which both the body and the mandrel are type 316 stainless steel or coated (plated or painted) types, should be used.

The use of fiberglass-encased plywood and wood for bulkheads, stringers, and engine beds is common in fiberglass boats. Metal fastenings in these members are susceptible to crevice corrosion, so coatings on the fasteners and sealants under the heads are recommended.

Fastenings in Other Fiber Reinforcements. Carbon fibers are both electrically conductive and highly noble. This has several implications for marine vessels. Less noble fastener metals in contact with carbon fibers and immersed in seawater will corrode. Two dissimilar metals in contact with the same carbon-fiber structure are in electrical contact with each other. If a common electrolyte is present, the less noble metal will corrode. Fasteners should be insulated from contact with the carbon fiber. Thick-wall electrical shrink tubing works well in such applications.

Sandwich core construction increases the rigidity of a structure by increasing its thickness-to-weight ratio. Sandwich core construction consists of thin, resin-impregnated fabric sheets bonded to a thicker lightweight core in between. Honeycomb cores are frequently used in bulkheads, overheads, cabin soles, cabinets, tables, and counters and are available with a variety of core materials, including aluminum. With aluminum cores, there is concern for galvanic corrosion with non-compatible fasteners. The article "Custom Sailing Yacht Design and Manufacture" in *Composites*, Volume 21, of *ASM Handbook*, 2001, provides details of sandwich core construction.

Steel hull boats will inevitably corrode in either fresh or saltwater, and for this reason, they are generally built with heavier-gage steel than is necessary for structural strength in their intended application to compensate for loss of strength as a result of corrosion. The use of a well-planned,

carefully applied and maintained epoxy paint system (grit blasting to white metal, anticorrosive primers, and protective topcoats) and the installation of an equally well-planned and maintained cathodic protection system will ensure long service.

Properly designed steel hulls allow rain or seawater coming aboard to drain freely to the bilges. Large limber and lightning holes are provided in floors, frames, struts, and stringers to facilitate both drainage and air circulation. The media used in grit blasting the hull must be free of contaminants. Beach sand will contain unacceptable levels of sodium chloride and other contaminants.

Well-planned cathodic protection requires the correct number and size of zinc anodes to be properly placed on the hull and then to be properly monitored and maintained (Ref 1). Mounting bolts should be welded to the hull to hold the zincs. The hull provides the connection, unlike wood or fiberglass hulls where wires are run from the anode to a common groundpoint.

Aluminum hulls of marine-grade aluminum-magnesium alloys (5000 series) are highly resistant to corrosion in both fresh- and saltwater. A properly designed and built unpainted aluminum hull will last indefinitely in saltwater, despite its reputation to the contrary. A number of small craft that were built from surplus aircraft aluminum-copper alloy (2000 series) after World War II and failed caused that reputation to persist today. The 2000 series is not as resistant to corrosion as other series, so it must be painted or clad for protection (Ref 3).

While it is not necessary to paint aluminum boats above the waterline, hulls must be painted below the waterline to prevent fouling by marine growth. The process consists of grit blasting, chemical cleaning, primer coat, two or more barrier coats, and then the antifouling coat. If the antifouling coat is a copper oxide bottom paint (not recommended), it must be applied over a thick epoxy-based barrier coat. Such a barrier coat is critically important to prevent galvanic interaction between the copper paint and the aluminum.

The interior surfaces of an aluminum hull, especially below the waterline, should also be painted to provide protection from galvanic corrosion caused by dissimilar metal objects falling into the bilge. Most noncommercial owners prefer to paint the topside for aesthetic reasons and to reduce glare and heating effects.

Aluminum is a highly active metal and less noble than any of the other metals commonly used for boats. Galvanic and electrolytic (stray current) corrosion is possible. Metal particles that may be trapped in grinding wheels or hand files—even a copper penny dropped in the bilge—can cause corrosive damage. Any copper bearing alloy, such as brass, bronze, or Monel, will cause corrosive damage unless appropriate precautions are taken. Dissimilar metals must be insulated from contact with the aluminum hull. Insulating pads of neoprene, wood, or some similarly electrically insulating material should

be used between the fitting and the aluminum. Fasteners should be coated with a polysulfide sealant or perhaps a zinc-rich primer before installing them to reduce, if not eliminate, any galvanic action between the fastening and the aluminum.

Underwater fittings, through-hulls (with proper backing blocks or built-up hull sections, and properly insulated), propeller and shaft, and rudder and rudder post will require cathodic protection, as with all types of hulls. Aluminum hulls in freshwater use magnesium anodes because of the lower conductivity of the water; in saltwater, zinc anodes are used.

Ferroceement hulls consist of a mild steel and wire mesh armature, plastered with Portland cement. Proper plastering mix and application will avoid future corrosion and structural problems. Galvanizing, professional plastering, moisture-inhibiting coatings, and, more recently, sophisticated concrete additives—plasticizer, pH control, cure-modifying agents, and even epoxy-coated frame and mesh—have overcome early problems of saltwater and oxygen migration through the cement to the armature. This caused extensive rusting. The rust, occupying many times the volume of the unrusted metal, can cause extensive cracking, which further exacerbates the problem.

A robust organic coating system will prevent moisture penetration to the steel armature and will prevent marine growth. The new epoxy-based coating systems have proved useful here; they bond and last well, especially when applied over an epoxy-tar-based primer.

Copper sheathing was once quite commonly used, especially in the tropics where marine borers (teredo worms) attacked wooden bottoms. Thanks to advances in the coating industry, copper sheathing is no longer required for underbody protection; toxic antifoulant coatings have provided a more convenient alternative. Copper sheathing is still being done, however, in restorations of classic vessels and also in special applications, such as for ice protection at the waterline in frigid latitudes.

The copper sheathing is typically quite thin (3 mm, or 0.125 in.) and fastened by copper nails. Galvanic corrosion is a serious consideration. Through-hulls, through-bolts, and other skin fittings must be of bronze or else isolated from contact with the copper sheathing.

Metal Deck Gear

Deck gear is the exterior fittings, fixtures, and structures used in operating or securing the vessel: cleats, mooring bitts, fairleads, pad eyes, lifeline stanchions, pulpits, towers, and ground tackle. Two types of corrosive damage are of concern: that which is primarily cosmetic and proceeds so slowly that sudden catastrophic failure is not likely; and that which can proceed undetected, fail suddenly, and present a safety hazard to the vessel or its crew. A freshwater

rinse of deck gear at the end of the day is good practice to reduce the effects of corrosion, as is occasional waxing.

Stainless steels (types 304 and 316) are used extensively in cleats, chocks, samson posts, handrails, davits, and a broad range of other deck hardware and furniture. They are so resistant to atmospheric corrosion that corrosion rates are not considered meaningful. Their greatest susceptibility is to pitting and crevice corrosion. Preventive measures consist of the avoidance of dings, dents, and scratches, which can be the sites for pit initiation.

Stainless steels are also susceptible to crevice corrosion at welds, lap joints, and under bolt heads. Welds, if not properly done—wrong filler metal or excessive heat—are particularly susceptible to intergranular corrosion (weld decay) and degradation of the strength of the joint. With purchased fittings, there is not much one can do about the welds.

Aluminum. Marine-grade aluminum alloys (5xxx and 6xxx series) have excellent resistance to atmospheric corrosion due to their tendency, like the stainless steels, to form a protective oxide film. Marine-grade aluminum, whose exposure is limited to the marine atmosphere, does not require painting if it is kept clean and not abused by repeated scratching, scraping, or chafing.

Most larger aluminum structures—towers, arches, davits, rub rails, handrails, and so on—are bright anodized and require little maintenance. Anodizing is an electrochemical process that produces a surface oxide (Al_2O_3 , or alumina) on the metal. This oxide surface is quite hard but can be scratched or rubbed off, eventually exposing bare aluminum that is then subject to pitting corrosion.

Stainless steel fastenings are commonly used with aluminum fittings. The stainless steel fastening is cathodic to the larger anodic aluminum structure. This is acceptable, because it satisfies the rule of cathode-anode area ratios, which states that the area of the cathodic metal must be small compared to that of the anodic metal. The smaller the area of the cathodic metal, the smaller the current draw and hence the smaller the corrosive damage to the anodic metal.

Galvanized steel deck and cockpit fittings are not considered attractive by the boating public, so their use is limited on recreational boats, but they are common on workboats and traditional craft. The service life of a galvanized steel fitting is a direct function of the thickness of the coating, so hot dip galvanizing is favored. Studies have shown that a fitting with a hot dip coating thickness of 0.076 mm (3 mils) may have a useful service life of between 30 and 35 years in a mild marine environment and between 10 and 15 years in a heavy industrial environment.

Bronze. For traditionalists, bronze is the preferred material. The excellent atmospheric corrosion resistance of bronze is due to a protective oxide film (cuprous oxide). This film forms very quickly on exposure to oxygen and

continues to build over time, reducing the corrosion rate.

Brass. The brasses are copper-zinc alloys. When the zinc content is greater than 15%, the alloy is susceptible to both dezincification and stress-corrosion cracking. However, when the zinc content is below 15% and when small amounts of tin and arsenic or antimony are added, resistance to both these forms of corrosion increases greatly.

Exposed brass tarnishes rapidly, developing the familiar greenish patina. It must be coated or polished frequently to maintain its characteristic bright, attractive finish. Plain, uncoated brass deck hardware is not very common. Brass is used mostly in light-duty cleats, chocks, vents, and housings and is almost always chrome plated.

Zinc Alloy. Some chrome-plated deck fittings—rail caps, flagstaff sockets, light-duty cleats, and chocks—often have a substrate metal of either zinc or Zamak (a zinc-aluminum alloy). These metals are used because they are inexpensive, are cast at low heat, and are easily die cast, producing parts with fine, sharp detail. They have only moderate strength, hardness, and corrosion resistance and, if the chrome plating should fail, are susceptible to serious degradation of their mechanical properties.

Equipment

Winches are complex assemblies with internals constructed from bronze, stainless steel, and, in some cases, anodized aluminum. These metals are not galvanically compatible. They are not sealed and are susceptible to penetration by saltair and seawater. The inevitable result is corrosion and abrasive wear of critical internal parts. A freshwater rinse will not eliminate the possibility of internal corrosion damage, and periodic servicing is required.

Backing plates are required on any fitting that is subject to large or sudden loads. They are especially important when the fitting is mounted on a relatively thin section, such as a fiberglass deck, cabin top, or coaming (Fig. 2). Backing plates are made of stainless steel, marine-grade aluminum, or plywood.

Susceptibility to atmospheric and galvanic corrosion must be considered. If fasteners are dissimilar metals, the two parts should be electrically insulated. If moisture is allowed to penetrate the space between the fastener threads, there may still be localized crevice corrosion, resulting in “frozen” fastenings. Thus, it is advisable to dip the fastening in some conformable substance, such as silicone or paint.

Lifeline Supports. Lifeline stanchions are usually stainless steel or anodized aluminum. Stanchions are typically inserted into a substantial cast metal base and pinned with a machine screw or cotter pin. Bases, for the most part, are stainless steel, chrome-plated bronze, or chrome-plated Zamak. There are several potential corrosion problems in this arrangement.

Because moisture can collect in the socket of the base, there is the potential for galvanic corrosion between the stanchion and the base and between the machine screw or cotter pin and both the stanchion and the base. It is important to be sure that these components can drain freely (Fig. 2) and are galvanically compatible.

Anchor Systems. The elements of the anchoring system are the anchor windlass, bow roller and accessories, chain, end fittings (shackles and thimbles), and the anchor itself.

Windlass. A typical anchor windlass may have parts made of aluminum, bronze, and both carbon and stainless steels. Its location in the bow of the boat subjects it to saltwater spray. Many windlasses have anodized or epoxy-coated aluminum above-deck housings. Corrosion damage to the housing itself consists of paint lifting, chafing, and abrasion on both painted and anodized finishes. Abrasion, mostly by the anchor rode, is the more serious, while galvanic corrosion between the fastenings and the housing must also be considered. Preventive measures consist of keeping the windlass covered when not in use, frequent wash-downs with freshwater, and coating the through-deck fastenings with heavy water-resistant grease or a corrosion inhibitor.

More serious than cosmetic and fastener problems are those that result from internal corrosion damage. Internal corrosion leads to increasingly degraded performance and, ultimately, to seizure of the windlass. If the windlass is electric, seizure can be dangerous, because the nonrotating windlass motor acts essentially as a dead short. Extremely high current can flow, resulting in overheating of the motor and the wires if not properly fused.

Windlasses depend on lubrication for protection from physical wear and corrosion. If left unused for long periods of time, these lubricants drain off metal surfaces, exposing them to the moist internal atmospheres created by condensation, and eventual corrosion. Keep the windlass properly oiled and lubricated, and operate it on a regular basis to keep these lubricants well distributed throughout the internals of the gear box and motor.

Bow Rollers and Accessories. Bow rollers, anchor chocks and brackets, and chain stoppers are exposed to constant saltwater soaking. These items should be of noncorrosive materials, such as stainless steels and Delrin. The bow roller

Fig. 2 A backing plate installation distributes stanchion forces. The drain hole in the stanchion base reduces a possible corrosive environment.

should be checked periodically for wear and corrosion of the roller shaft, and all through-deck fastenings should be inspected periodically for corrosion and/or loose nuts.

Chain may be made of low-carbon steel, high-carbon steel, or stainless steel. Hot dip galvanized steels are preferred over electroplated finishes. The actual service life of a hot dipped galvanized chain is dependent on the local conditions but is typically between three and five years.

Stainless steel, typically type 316, has much superior corrosion resistance and is some 10 to 20% stronger than low-carbon steel chains. Corrosion damage to the stainless steel is minimal under normal conditions of immersion in free-flowing seawater. When marine growth is allowed to accumulate on the chain, denying access to the fresh supply of oxygen needed to form a protective coating, pitting and crevice corrosion can result.

The greatest damage to the chain in anchoring or mooring systems results from the wear and abrasion that take place at the bottom end of the mooring or anchor rode. As current and tides change direction and the boat swings on its anchor, the links at the bottom of the chain—and the end fittings—can suffer considerable wear and accelerated corrosion rates. Reversing the chain end-for-end each year, to even out the wear, can significantly extend its useful life.

Thimbles and shackles are available in both galvanized carbon steel and stainless steel (type 18-8 or 316). The greatest wear in the anchor system takes place here, so these are the most common failure points. The physical wear quickly removes the galvanizing, exposing unprotected metal, which quickly forms a soft layer of rust that is rapidly worn away. Little can be done to prevent this, so using larger end fittings will give a longer service life.

Dissimilar metals in ground tackle applications—stainless steel end fittings with galvanized chain and anchors—should be analyzed for cathode-to-anode area ratio, which should be very low (small cathode, large anode). For example, an 8 mm ($\frac{5}{16}$ in.) stainless steel shackle on a 15 m (50 ft), 8 mm ($\frac{5}{16}$ in.) galvanized chain has a ratio of the cathode (stainless shackle) area to anode (galvanized chain) of roughly 1 to 77. Thus, while there may be some localized corrosion at the point of contact, neither the chain nor the shackle will suffer severe corrosive damage, and reasonable service life can be expected.

Anchors are low-maintenance items available in galvanized (hot dipped preferred) steel, stainless steel, aluminum, and titanium.

Propulsion Systems

Propulsion systems include engines, lubrication, cooling, exhaust systems, propellers and propeller shafts, and the rudder. Single-metal uniform corrosion thrives when metals high in

the galvanic series, such as mild steel and iron, are exposed to moisture, especially salt-laden moist air. When dissimilar metals, such as aluminum pistons, rods and heads, iron blocks, steel cylinder liners, and copper alloy freeze plugs, are in contact with each other and immersed in the same body of water, galvanic corrosion will also occur. Also, the presence of acids and elevated temperatures can exacerbate and accelerate corrosive damage. All of these conditions exist in internal combustion engines.

Inboard Engines. Engine blocks are large iron castings. Cylinder liners are made of steel with highly polished inner surfaces. Lubricating oil is splashed up onto the inner surfaces of the cylinder liner walls to lubricate the piston travel. As rings wear, some blow-by occurs, resulting in acid contamination of the oil in the oil pan and corrosive attack of cylinder walls and bearings. Pitting of the cylinder walls can also result from cavitation erosion, which can take place on the outer surface of the cylinder liner. This occurs when combustion in the cylinder causes vibration of the cylinder wall (liner), creating vapor bubbles in the coolant fluid. These bubbles then collapse, ultimately removing the protective oxide layer of the metal, leaving it vulnerable to corrosion and pitting of the cylinder liner.

Boats that sit idle for considerable periods of time without running their engines also are subject to corrosive damage. Protective lubricating oil that normally coats metal surfaces gradually drains down, exposing these surfaces to moist, salt-laden air, and the inevitable corrosion begins to take place. This is more likely to occur in diesel engines, because the residual amounts of sulfur are likely to be greater in diesel fuel than in gasoline, especially in certain parts of the world where pollution controls are not stringent. The engines should be run on a regular basis (weekly) to maintain lubrication in the engine and bearings.

Electrical engine components should be mounted as high as possible to avoid water sloshing around in the bilge. Alternators are particularly susceptible to corrosion from moist saltair on terminals and brush springs. A common source of problems is corroded terminals and wire connections in the ignition system. It is a good idea to spray them occasionally with one of the commercially available moisture-displacing lubricants designed for this purpose.

Outboards/Outdrives. The engine blocks in outboards and outdrives are generally of die-cast aluminum. Outboard motor housings, once exclusively aluminum, are now more commonly made of high-impact plastics. The primary form of protection for aluminum outboard motor housings is in the decorative coatings. Typically, there is an epoxy primer undercoating, a decorative epoxy paint, and a clear coating. Chips, scratches, and dents will result in rapid local corrosive attack.

The lower unit is protected by one or more sacrificial anodes most commonly zinc, located below the waterline. Magnesium anodes are also available for motors that are used in freshwater.

These must be monitored and replaced when they are no more than 50% depleted.

Frequent flushing of the cooling system is highly recommended, and thorough flushing before storing for the winter is a must.

Lubricating oils reduce wear and also perform functions such as acid neutralization, contaminant suspension, and rust and corrosion inhibition. Additives in the oil enhance these properties. The proper choice and timely replacement of engine oils is important to ensure a reliable and satisfactory life for an engine. In the course of engine operation, products of combustion, wear, and corrosion end up in the oil in the sump. Laboratory spectrographic analysis of a sample of the engine oil can reveal a tremendous amount of information concerning the condition of the engine.

Cooling Systems. There are two basic types of cooling systems in common use in marine engines: once-through systems and closed recirculating systems. In once-through systems, the cooling water passes through the system to be cooled only once and is then discharged. These systems are referred to as direct cooling or raw water systems, because the cooling water is taken from rivers, lakes, or the ocean in which the boat operates. Closed recirculating systems, also referred to as indirect or freshwater cooling systems, continuously recirculate the same water. The heat that is transferred to the recirculated water is subsequently transferred to a second and separate cooling stream through a heat exchanger. Corrosion by-products can accumulate and foul heat-transfer surfaces; however, these systems are amenable to the use of corrosion-inhibiting additives.

To reduce galvanic corrosion, engine manufacturers make provision for the insertion of sacrificial zinc anodes in the cooling system. Figure 3(a) shows a complete engine zinc anode

(a)

(b)

Fig. 3 Zinc sacrificial anodes for an engine cooling system. (a) Engine anode. (b) Replacement pencil anode

assembly. From the outside, the assembly looks like a pipe plug threaded into the block. The replaceable zinc “pencil” (Fig. 3b) threads into the internal end of the anode assembly. Most engines have two or more engine zincs. These should be checked on a regular basis, at least a couple of times a year.

Raw water systems have performed successfully for over 20 years in some very rugged saltwater service, such as commercial fishing boats (Fig. 4a). The engines are designed for raw water cooling, with heavier castings, larger cooling water passages, and thicker wall sections. Failures, when they do occur, are typically in the manifold. The systems are susceptible to clogging and blockage from silt, sand, marine growth, rust, and scale. The silt and sand, if allowed to settle for significant periods of time, can result in poulitice corrosion. The sand can cause impingement erosion at elbows or sharp turns in the piping. Raw water systems require regular maintenance; cooling water passages must be kept open, pumps must be inspected for impingement erosion, the impellers must be changed regularly, and filters and thermostats must be kept clean.

The *freshwater cooling system* is a superior system (Fig. 4b), because the engine operates at a more constant and efficient temperature. Silt,

sand, and salt are kept out of the engine. Antifreeze with corrosion-inhibiting additives is used, which makes year-round use of the boat practical. Antifreeze products are based on either ethylene glycol (toxic) or propylene glycol (nontoxic and biodegradable). The coolant fluid in the engine consists of a mixture of 50 to 70% antifreeze and freshwater. Freshwater contains considerable quantities of free oxygen. As the coolant is circulated around the closed, pressurized system and repeatedly heated and cooled, the oxygen content is reduced to negligible levels, which reduces corrosion. To take advantage of this feature of the closed freshwater system, it is a good idea to change the cooling fluid only when necessary, say once a year at winter layup.

The most common form of corrosion in the heat exchanger occurs under sediment deposits. If debris gets by the screens and filters and become lodged in the tubes, it can cause turbulence downstream, which can result in pinholes in the tubes. Water velocities of less than 0.9 m/s (3 ft/s) are not sufficient to prevent sediment buildup, biological fouling, or clogging from small bits of debris collecting in the tubes. Excessive water velocities can cause erosion and impingement damage. Velocities of 1.5 to 1.8 m/s (5 to 6 ft/s) for seawater applications are excessive for copper, but most other commonly used alloys perform well up to 2.7 m/s (9 ft/s). Stainless steels, either type 304 or 316, are not suitable for seawater heat exchanger applications. The alloy of choice for heat exchanger tube applications is 70–30 cupronickel.

Heat exchangers should be periodically flushed out to remove sediment and debris. In brackish, inshore estuarial waters, where there is a lot of silt, mud, and sand, monthly flushings may be required. In clean waters, flushing, disassembly, and brushing at the annual layup is sufficient. Leaving water in a heat exchanger for any significant period of time is highly conducive to corrosion. The water becomes stagnant, bacteria colonies form, microbiologically influenced corrosion results, and crevice corrosion will take place under sediment deposits. Details are found in “Microbiologically Influenced Corrosion” in *ASM Handbook*, Volume 13A, 2003, p 398 to 416.

Heat exchangers are typically fitted inside the boat in the engine room. Another type of heat exchanger, the keel cooler, is mounted outside the boat on the side of the keel or on the underbody (Fig. 5). There is no housing; the tubes

themselves are exposed to the water in which the boat is operating.

Exhaust Systems. Exhaust gases are hot, noisy, noxious, toxic, and corrosive. The exhaust must be moved away from the crew, out of the boat, and quieted down in the process. This must be done without restricting the exhaust flow, which would increase the backpressure. The system must be able to withstand the acidic by-products of combustion and the corrosive saltwater coolant at elevated temperatures (Ref 4). There are two basic types of exhaust systems (with some variations): the wet exhaust system and the dry exhaust system.

Wet Exhaust System. Figure 6(a) shows a typical wet exhaust system such as found in a power cruiser where the engine is mounted above the waterline. In this type of system, raw cooling water is injected into the exhaust gas flow after it leaves the manifold and on the downside of the riser. There, it mixes with the exhaust gases, greatly reducing the temperature of the gases. The exhaust stream is then carried through a silencer (or muffler) to the exhaust outlet at the transom and discharged. Sharp and abrupt turns in the system are to be avoided after the cooling water is injected into the system to minimize opportunities for erosion-corrosion damage and backpressure on the engine. The section of the system before the cooling water injection point is hot and must be insulated. If the exhaust drop height is not sufficient to ensure the highest point is above the waterline at all angles of heel, as in the case of sailboats, a riser must be added (Fig. 6b).

Dry exhaust systems are used primarily on commercial and high-performance craft (Fig. 6c). The entire run from the manifold to the outlet is extremely hot; it must be well shielded to prevent burns to both the boat and the crew. When wood is periodically exposed to very hot surfaces (120 °C, or 250 °F) over a long period of time without a significant flow of air, a form of carbon may develop, called pyrophoric carbon, that can be extremely dangerous.

Exhaust Riser. For high temperatures and galvanic compatibility, metallic piping is necessary for components in the dry section between the manifold and the cooling water injection point. Iron is still commonly used for threaded nipples, elbows, and injection elbows.

A *siphon break*, or vented loop, consists of a tube, connected between the outlet of the raw water pump and the raw water injection point, with an air-admitting valve at the top of the loop. Generally, the valve fails due to corrosion. Clogging by salt crystals and other debris leads to sticking in the open or closed position.

Traditionally, the metallic components in the dry section of the exhaust have been schedule-80 cast iron. This is a robust material that is galvanically compatible with the commonly used cast iron manifolds. It is, however, susceptible to rusting and scaling that can break loose and clog the cooling water injection orifices, resulting in overheating. Alternative alloys have shortcomings in the area of galvanic compatibility or

Fig. 4 Engine cooling water systems. (a) Raw water system. (b) Freshwater system

Fig. 5 Keel heat exchanger installation

corrosion resistance. Aluminum, while it would be compatible with engines having aluminum manifolds, is not as hard or as strong as cast iron and poses galvanic compatibility problems with other fittings. Bronze has compatibility problems with both iron and aluminum, is relatively soft, and has a higher susceptibility to erosion- and impingement-corrosion. Also, it is aggressively attacked by the sulfuric acid from residual sulfur in fuels, especially diesel fuels. Most of the common grades of stainless steel (types 18-8, 302, and 304) will corrode if used in wet exhaust systems. Type 316L is sometimes used, but its performance is marginal. Some of the more exotic nickel-base alloys, such as Hastelloy C,

Inconel 625, and Incoloy 825, are excellent, but cost limits their use.

Piping. After the point of cooling water injection, wire-reinforced marine exhaust hose is preferable for use in the exhaust line. Hose joints should be double-clamped with all-stainless-steel hose clamps.

Mufflers/Silencers. In the marine industry, mufflers are frequently referred to as silencers, and the terms are used interchangeably. Mufflers are seldom used in dry exhaust systems. When they are used on workboats, because there is no cooling water to bring the temperature down within the range of the nonmetallic materials, stainless steel and hard aluminum are frequently

the materials of choice. Corrosion, aside from atmospheric effects, is not a significant problem in these systems.

Propeller, Propeller Shaft, and Rudder. Principal materials used in propellers are Nibral (nickel, aluminum, and bronze alloy) and cast manganese bronze. Nibral is excellent but more expensive. Most propellers are manganese bronze. Manganese bronze (58Cu-39Zn) is really a brass and is subject to dezincification. Popular materials for propeller shafts are stainless steel and Tobin (naval) bronze.

High-performance stainless steels, while more expensive than the conventional austenitics, have found significant use in marine applications. Typical of this group is UNS S20910 (22Cr-13Ni-5Mn), a nitrogen-strengthened grade with superior corrosion resistance. The pitting resistance number (PREN) is 35.7, compared to UNS S31600 with PREN of 32, and it has approximately twice the yield strength. This grade is used in boat shafting, fastenings, and marine hardware. Nitronic 50 (UNS S20910), with a yield strength of 345 MPa (50 ksi), and Aquamet 22, with a yield strength of 896 MPa (130 ksi), are essentially the same alloy, except that the Aquamet grades 17, 18, 19, and 22 are hardened for propeller shaft applications. Nitronic 50 is widely used in sailboat rigging, chains, fasteners, pumps, and other applications.

Another grade of stainless steel that has found wide use in recreational and workboats as propeller and pump shafting, hydrofoil struts, and other marine applications is UNS S17400 (17-4 PH), precipitation-hardening martensitic grade. Corrosion resistance is approximately the same as UNS S30400 (PREN 20); however, yield strength at 1262 MPa (183 ksi) is more than five times that of UNS S30400.

Increasingly stringent environmental and pollution regulations have increased the use of stainless steels. Development efforts have followed two basic approaches. Increased chromium and nitrogen content with a microstructure that is approximately equal parts of austenite and ferrite is referred to as the duplex grade. The other approach was based primarily on increased molybdenum content while retaining the austenite microstructure. This is referred to as the superaustenitic grade. Both approaches depended heavily on increased nitrogen content and control made possible by the development of argon-oxygen decarburization processing.

The duplex grades have better resistance to pitting and crevice corrosion (PREN 39) and to chloride stress-corrosion cracking. They are used primarily in the offshore oil and gas industry. The duplex grades include UNS S31803 (2205), with a yield strength of 517 MPa (75 ksi), and UNS S32550 (255), also called Ferralium 255, with a yield strength of 675 MPa (98 ksi).

The superaustenitics, also referred to as the 6 Mo stainless steels, are outstanding marine metals. They have the best corrosion resistance of all, with an average PREN of 44.4, and excellent strength. Typical grades are UNS S31254 (254 SMO) and UNS S32654

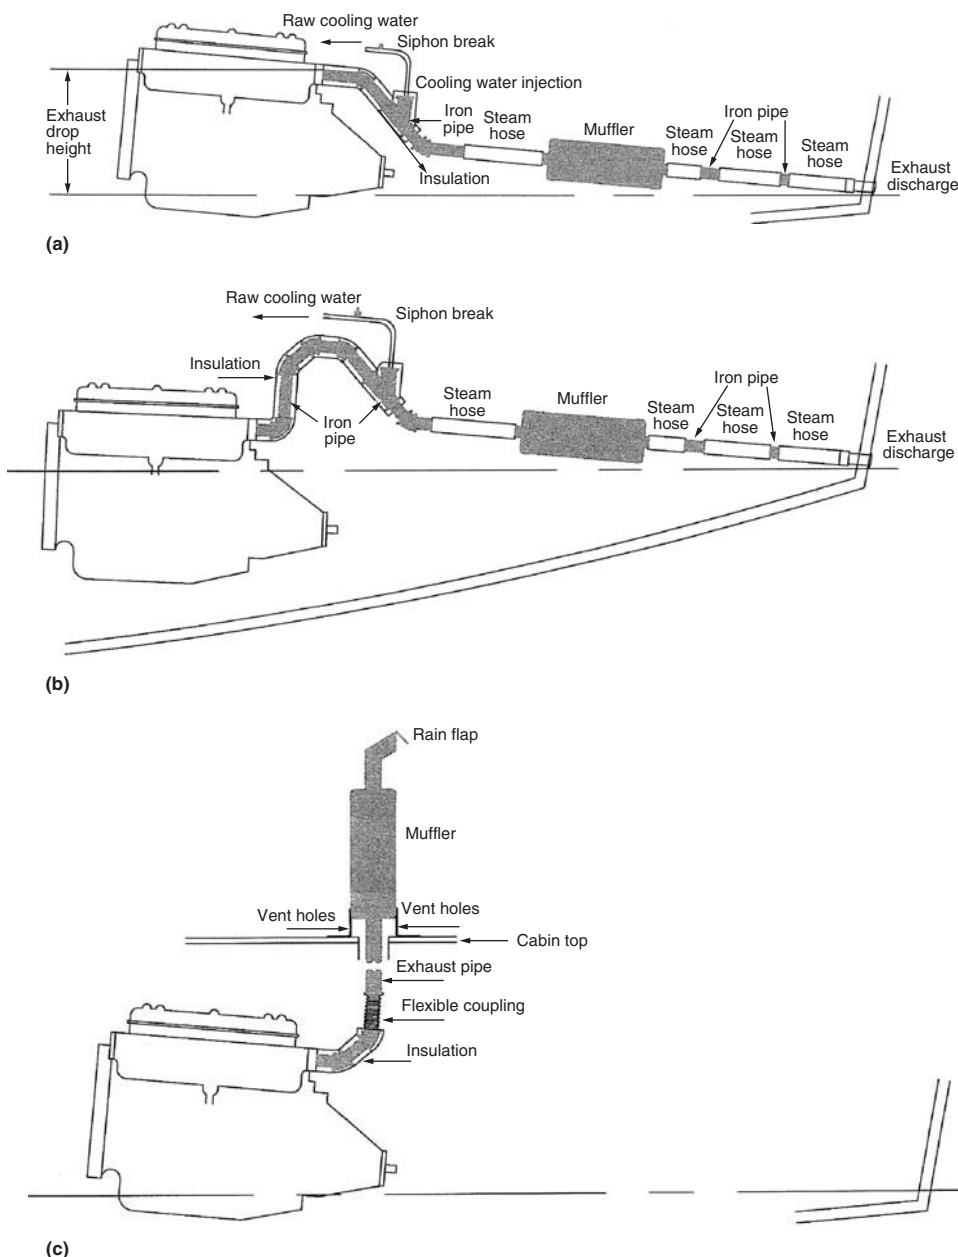

Fig. 6 Exhaust systems. (a) Traditional wet system. (b) Sailboat wet system. (c) Dry system

(654 SMO), with yield strengths of 300 MPa (44 ksi) and 425 MPa (62 ksi), respectively.

While the duplex and superaustenitic alloys have found significant and increasing use in the offshore oil and gas industry, they have thus far made no real penetration into the highly competitive small-boat market because of cost. However, with their superior properties, use is expected to increase on boats.

Tobin bronze, which is roughly 60% Cu and 39% Zn, is, like manganese bronze, subject to dezincification. Bronze propellers on stainless steel shafts require cathodic protection. The propeller, propeller shaft, and rudder assembly can be protected by the use of zinc anodes. The collar zinc, such as that shown in Fig. 7(a), is installed on the propeller shaft. Zinc anodes may also be attached to the struts. The propeller nut zinc, such as that shown in Fig. 7(b), is also sometimes used on the end of the propeller shaft behind the propeller nut.

Alternatively, one or more zinc anodes can be mounted on the outside of the hull in proximity to and in line of sight of the shaft and propeller and then connected electrically to the propeller and shaft (Fig. 8). A wire is run between the zinc mounting bolts on the inside of the hull and the electrical system common ground on the engine block (frequently an engine mounting bolt). This method has a couple of advantages over direct mounting of the zinc on the fitting to be protected. It provides a broader distribution of the ion exchange field and more uniform protection over the surface of the fitting. Also, by electrically connecting other underwater fittings to the common groundpoint, they too will receive cathodic protection from the zincs.

(a)

(b)

Fig. 7 Zinc sacrificial anodes. (a) Shaft collar zincs are used on immersed exposed propeller and rudder shafts. (b) A propeller nut zinc is threaded onto the end of the propeller shaft

The effectiveness of the cathodic protection system depends on low-resistance electrical paths. Conductors of adequate size and high-conductivity splices and contacts are needed. Connecting the wire to the engine block and relying on the conductivity of the block, transmission housing, and shaft coupling is not satisfactory. The electrical resistance of this path is high and not reliable, especially where a flexible shaft coupling is used. The connection to the shaft should be made through a spring-loaded phosphor bronze shaft brush. If the rudder and rudder stock are to be included in this protection system, the rudder stock must also be connected.

Zinc anodes work best when they are directly attached to the metal they are protecting. In this case, a plate-type zinc, similar to that shown in Fig. 8(a), is commonly used. Single anodes with all of the fittings connected to them provide uniform protection, because the potential is the same. With separate zincs on different fittings, some could be overprotected while others may not be receiving enough protection. Most importantly, the anodes must not be painted. Anodes that have through-holes in them for fastening will fall off as the zinc corrodes and the holes open up. The zinc should have a cast-in

(a)

(b)

(c)

Fig. 8 Zinc sacrificial anodes for the boat underbody. (a) Remote zinc plate. (b) Teardrop zinc. (c) Remote plate installation

plate and fasteners, typically of stainless steel, to prevent this.

The zinc and its through-bolts should be insulated from the wood hull to reduce the possibility of alkali damage to the wood. A teardrop-shaped zinc (Fig. 8b) mounted on, but insulated from, a fairing block reasonably close to the metals it is protecting would be ideal. It should be located so that it will not disturb the smooth flow of water to the propeller, and it should be immersed at all times.

Electrical and Electronic Systems

No other system on the boat is as susceptible to performance-degrading corrosive damage as the electrical and electronic systems and equipment. Components contain many dissimilar alloys and nonmetals in intimate contact. Components are in atmospheres that range from total immersion in the bilge to high humidity, high temperature in the engine room to the salt-laden, spray-soaked flybridge or tuna towers. Because of their increased complexity, smaller size, closer spacings in circuitry and components, and sensitivity to high temperatures, extremely low levels of corrosive contaminants can cause degradation or complete failure in modern electronic equipment.

It is helpful to think about the electrical system in terms of its separate functions: power generation and maintenance, control and distribution, and the loads or devices that it serves.

Power Generation and Maintenance. All loads perform at their best when they have a full 12 V at their terminals. Because there is only 12.5 V on a fully charged battery, minimizing voltage loss by using high-quality copper marine battery cables of 33 mm² (0.05 in.²) (American wire gage, or AWG, 2) size is recommended. Automotive or welding cable and clamp-on or solder-on battery clamps are not satisfactory. Preassembled marine cables consist of heavy-duty tinned copper terminal ends and tinned fine-strand copper wire. The ends are molded in an extrathick coating of plastic to prevent water from wicking up into the cable, causing corrosion, increasing resistance, and resulting in cable deterioration and a safety hazard.

Distribution and Control. The distribution panel is the key element in the distribution and control of electrical power to the loads. Typically, it consists of a baked enamel or anodized aluminum panel with circuit protection devices, terminal blocks, and other electrical components mounted on it. The circuit protection devices may be either fuses and toggle switches or circuit breakers. The panel may also contain voltage and current meters. It may be as simple as a six circuit fuse and toggle switch panel or as complex as the 28 branch alternating current (ac) and direct current (dc) instrumented circuit breaker panel shown in Fig. 9(a).

Figure 9(b) shows the back panel wiring for an 11 m (36 ft) inshore commercial workboat,

skipped by a hardworking fisherman who did not have time for the electrical niceties. Moisture penetrates into all cracks and crevices—wire splices, butt connectors, screw contacts, fuse blocks, and even nonmarine-grade circuit breakers. Contacts and mating surfaces oxidize, resistance increases, voltage is lost, and heat is generated. At best, performance deteriorates or equipment fails; at worst, the possibility of fire exists. This boat also had a severe stray current corrosion problem.

The distribution panel should be located high above the bilge in a dry, protected location. The enclosure should provide for drainage at the bottom and ventilation at the top. Cable and wire access should be from the side and should lead down and away from the enclosure, forming drip

(a)

(b)

Fig. 9 Electrical power distribution. (a) 28 branch alternating current and direct current circuit breaker panel. (b) Wiring for an 11 m (36 ft) workboat without distribution panel

loops (Fig. 10). After all contacts, connections, and metal surfaces are clean and properly made up, a moisture-displacing corrosion-preventive spray should be used.

Wiring and Loads. The only wire that should be used in the boat electrical system is marine-grade multistrand tinned copper wire with a heavy protective sheathing. Consult standards such as Ref 5 or 6. Solid conductor wire simply does not stand up well to the considerable vibration and occasional severe dynamic shock experience on boats, and it also tends to work harden and fracture. This can cause hard-to-find faults. Multistrand wire has more and finer strands and is therefore more flexible and better able to withstand the shock and vibration. Each individual strand is tinned to better withstand the corrosive atmosphere.

If cable ends are unsealed, moisture tends to wick between wire strands under the insulation, causing corrosion and accelerating failure.

Wire sheathing types TW, THW, and THWN (thermoplastic sheathing) are recommended by the American Boat and Yacht Council (ABYC) for general wiring applications, type XHHW (cross-linked polymer sheathing) for high-heat areas, and MTW, which is also oil resistant, for engine room applications. These wires should be type 2 or 3.

Solder Splices. When properly made, soldered splices consisting of two (or more) wires twisted together, soldered, encapsulated in electrician's putty or some other moisture-excluding plastic encapsulation, then covered with either heat-shrink tube or high-dielectric plastic tape, or both, can provide long service. If improperly made, the result is a high-resistance connection; excessive heat results, the solder softens or melts, and the splice comes apart. Soldering, in effect, transforms the flexible-stranded conductor into a solid conductor with its susceptibility to fatigue failure. The ABYC standards do not allow solder to be used as the sole means of mechanical connection of wires.

Crimp connectors, encapsulated to prevent moisture penetration and covered with shrink tube, are preferred. There are three types of

crimp terminals: ring, captive spade, and spade terminals. The ring-type terminal is generally recommended, because it cannot come off the stud (screw terminal) if the fastening becomes loose, as the spade terminal may. However, this type of terminal requires the complete removal of the retaining screw or the nut on the stud, and the nut or screw, when removed, can fall into the bilge. For this reason, many prefer the captive spade whose upturned ends assist in preventing this. In-line crimp connectors are also used to connect wires.

There are basically two ways to make a completely airtight and waterproof crimped connection. The first is to use a terminal or connector with an adhesive-lined heat-shrink sleeve. The sleeve should overlap the terminal end, so that when heated, the shrink tube covers the ends of the terminal, making a waterproof fitting. Alternatively, a regular nylon-insulated crimp-type connector can be used but covered with adhesive-lined heat-shrink tubing.

Wire nuts, such as those commonly used in household wiring, should never be used in marine wiring. Typically, the threaded metal insert in these devices is of mild steel and is subject to rusting and a degraded connection.

Electronic equipment includes a wide variety of metals and alloys. Printed circuit boards alone may contain copper, copper alloys, copper-clad materials, electroplating, solder, tin, and lead. Electrical contacts may consist of copper alloys, clad steels, gold, palladium, silver, and tin. Connectors may use beryllium-copper, stainless steels, gold, palladium, silver, and tin. Switches and relays include copper alloys, steels, stainless steels, electroplating, and various contact surface materials. Electronic equipment is highly susceptible to both single-metal (atmospheric) and galvanic corrosion. Many manufacturers of electronic equipment use sealed enclosures to prevent corrosion. Even so, moisture intrusion continues to be a problem. The relative humidity inside the box must remain below 40% to ensure that corrosion problems do not occur. Electronic equipment that uses forced ventilation (fans) from the ambient atmosphere for cooling should be avoided in marine atmospheres. This type of cooling will greatly accelerate corrosion as a result of the moist saltair circulating in intimate contact with the internal circuitry.

Electronic equipment used on boats should be designed for marine applications. Such designs include encapsulated components and protective conformal coatings on printed circuit boards. The printed circuit boards should be mounted vertically above the bottom of the enclosure to prevent moisture accumulation. Cable entries should be on the sides of the box (not the bottom), and cabling should lead down and away from their connectors and be arranged to form drip loops in the cable runs (Fig. 10). Small, sealed packages of desiccant may be placed inside enclosures to absorb moisture during shipping and storage. Often, the desiccant is a salt (lithium chloride) that eventually

Fig. 10 Typical cable drip loop to prevent water entry into a hollow mast

becomes saturated, leaving a soggy bag of salt inside the equipment, so these should be removed.

Electrical contacts are especially susceptible to corrosive damage. This is due to the low connector contact force and the low voltage, which result in greater sensitivity to tiny amounts of corrosion products and contaminants. Typically, the material in these contact surfaces is tin, gold, or silver plating. Tin plating is susceptible to oxide formation that increases the contact resistance. Most frequently, failure of this type of contact is due to fretting corrosion, that is, repeated oxidation of the contact surfaces due to vibration and minute movement of the contact surfaces. Gold is not subject to atmospheric corrosion. Due to economic and mechanical considerations, the gold plating is usually very thin and has pores at which galvanic corrosion can occur in marine atmospheres. This can seriously degrade the contact surfaces and result in poor or intermittent contact. Silver has, at times, been used as an underplating for the gold. However, it was found that if there were any sulfides in the environment, the contacts deteriorated rapidly. Nickel plating of contacts has proved effective in reducing these effects. Preventive methods are limited to preventing moisture penetration, providing good mechanical support with strain relief at the connector, and ensuring that all coaxial connectors are properly made up and sealed.

Printed circuit board corrosion is minimized with a protective conformal coating, a sprayed plastic type of film that forms a physical barrier against moisture and contaminants.

Bonding, Grounding, and Lightning Protection. Bonding is the practice of electrically connecting the exposed metallic non-current-carrying components on the boat to the common groundpoint of the boat dc electrical system, which is in turn connected to the boat sacrificial anodes. This includes the engine, transmission, propeller and shaft, metal tanks, metal housings of motors, generators and pumps, metal cabinets, and, in short, all large metal objects. The bonding conductor must be of very heavy-gage copper, at least AWG 8, and the sacrificial anodes must be sufficiently massive to protect all of the metals that are immersed—wholly or partially—in seawater. The objective is to eliminate the possibility of any electrical difference of potential between them. There are basically three reasons for bonding: electrical system grounding, lightning protection, and corrosion protection.

The grounding jumper wire provides a low-resistance path to ground, holding the equipment case at ground potential, eliminating the danger of shock and ignition, and reducing the possibility of corrosion due to stray electrical currents.

The lightning protection system consists of an air terminal mounted at the top of the mast and a heavy down conductor—AWG 6 at a minimum—run in as short, straight, and direct a path as possible to a groundplate mounted externally on the vessel bottom. An interconnecting con-

ductor of at least AWG 8 should be connected between the down conductor and large metal objects within 1.8 m (6 ft) of the down conductor to reduce side flashes. This system forms a zone of protection around the boat. The zone of protection has a base radius equal to the height of the air terminal above the water. It must be high enough so that a line drawn from the top of the air terminal down to the water at a 45° angle does not intersect any part of the boat. If this system is properly implemented and the boat is in the water, anyone or anything within the zone of protection will receive some degree of protection. See Ref 7 for details.

Plumbing Systems

In older boats, it was common practice to use steel (carbon or stainless), aluminum or copper tanks, copper or iron piping and fittings, and brass or iron valves. Today, a wide variety of advanced plastic materials have supplanted these corrosion-susceptible metals. Thus, what one can expect in the way of corrosion problems on a boat depends in large measure on the age of the boat and its plumbing.

Freshwater Systems

A typical pressurized freshwater system consists of one or more water storage tanks and a pump—activated by an integral pressure switch—that draws water from the tanks when an opened tap drops the pressure.

Freshwater Tanks. Of the various metals used to construct potable water tanks—carbon steel, stainless steel, aluminum, and copper—none is without definite limitations and shortcomings. All are susceptible to some form of corrosion.

Carbon steel in damp atmospheres is highly susceptible to corrosion, that is, rusting, and requires some sort of specially formulated coating to ensure long-term satisfactory performance.

Stainless steel depends on the availability of a fresh supply of oxygen to sustain the chromium oxide protective film. When held against a moist or damp material, such as support blocks and straps, the necessary supply of oxygen is denied, and the metal is subject to corrosive damage in that area. (Aluminum suffers from this same dependency.) Also, potable water, by definition, is freshwater in which the chloride content is less than 250 ppm by U. S. standards and less than 350 ppm by World Health Organization standards. However, city water may contain chloride levels of 1500 ppm or even higher, depending on the source. This can cause pitting or crevice attack in stainless steels. One should also be concerned about traces of bacteria in the water supply, because stainless steel is susceptible to microbiologically influenced corrosion. Regular flushing of the system a couple of times each season is recommended.

Galvanized Steel. Galvanized tanks have also been used in the past, although their use has been generally discontinued.

Copper was also used quite frequently for water tanks in older boats, because protective films typically form on the surface. However, in soft waters—water with little or no mineral content—these protective films are not able to form, and copper corrosion rates can become significant. A greater concern with the use of copper tanks is the solder used in their fabrication. This can result in dangerously high concentrations of lead in the water, which can represent a serious health hazard. Copper use has fallen quite sharply in recent years, and more attractive alternatives to copper tanks are available.

Aluminum is a popular choice for water tanks. Aluminum and its alloys are lightweight, easy to fabricate, of moderate cost (especially when compared to stainless steel and Monel), and have good corrosion resistance (except for the copper bearing grades, the UNS A92000 and A02000 series) to freshwater. However, much depends on the specific water chemistry. Aluminum is very susceptible to attack by certain heavy metal ions, particularly iron, copper, and lead. Slight concentrations of even a few parts per million will cause severe pitting. Copper tubing upstream of aluminum tanks can easily contain such concentrations. Also, aluminum is highly susceptible to severe pitting resulting from poultice corrosion. This happens when damp organic materials, such as insulation under restraining straps, wood blocking (especially oak), and accumulations of dirt and debris, are in contact with the tank.

Monel is the premium material from which to fabricate water tanks. While more expensive than other metals, it is stronger, far less susceptible to corrosion, and does not impart strange flavors to the water.

Fiberglass. Built-in fiberglass water tanks are frequently used in fiberglass boats.

Polyethylene. Thick-wall high-density polyethylene is an extremely attractive material for water tanks.

Piping. Iron, stainless steel, rubber, clear plastic, or copper were used in older boats. In more recent years, the use of plastic piping is more likely.

Copper. The preceding comments concerning copper tanks also apply to copper tubing. Copper tubing is also very susceptible to impingement corrosion, the erosion that occurs in fast-flowing turbulent water. Furthermore, copper is still subject to corrosion—atmospheric, galvanic, and stray current. There are more attractive alternatives.

Clear plastic vinyl hose is not an attractive alternative, despite the fact that it has been used extensively for quite some time. Clear hose admits light, and this fosters the growth of mold, fungi, and bacteria.

Polybutylene, a plastic resin, was used extensively in the production of water piping from approximately 1979 until approximately

1995. However, oxidants, such as chlorine, react with the polybutylene, causing it to become brittle and develop tiny cracks. The strength of the pipe is seriously diminished and subject to sudden failure. Polybutylene has been abandoned.

Rigid opaque plastic tubing makes excellent water piping. This is the popular polyvinyl chloride and chlorinated polyvinyl chloride plastic tubing and fittings that are increasingly familiar to both homeowners and the boating community. Because it is opaque, mold, fungi, and bacteria are not a problem. It is easier to work with than copper tubing. No solder (or lead) is involved; joints are glued. It does require isolation from shock and vibration.

Flexible opaque plastic tubing suitable for potable water systems is a more recent development. One such hose is referred to as PEX hose, which stands for polyethylene, cross linked. Cross linking refers to the molecular structure of the material and results in considerably increased strength. This is a very attractive alternative to the older materials discussed previously. It is strong, flexible, and easy to lay out and plumb. It will not corrode, and it is opaque, so there are no mold or fungi problems. A similar polyethylene tubing, although not cross linked, is also available commercially. Although not as strong as PEX, its strength is more than adequate for marine freshwater piping applications, and it is more flexible. Both materials are excellent piping materials for marine use in both hot and cold water systems.

Pumps. The pump most commonly used in freshwater systems is the diaphragm pump. Corrosion problems are primarily limited to the housings, which are typically aluminum, and to the fastenings, which are typically stainless steel. This often results in seized fastenings that make the pump difficult to disassemble for simple repairs and cleaning. Also, if wires, contacts, or connections are corroded, voltage at the pump will be lower than it should be, and the pump will run slowly and overheat.

Accumulator tanks may be made of stainless or coated steel, nylon, or acrylonitrile-butadiene-styrene plastic. Corrosion considerations are essentially the same as for water tanks.

Hot Water Tanks. Typical marine water heaters consist of an inner tank, with an inlet fitting at the bottom and an outlet at the top, surrounded by a layer of insulation and all enclosed within a protective shell. An electric heating element is mounted through an access panel on the side of the heater shell. Protective outer shells may be made of stainless steel, coated carbon steel, or polyurethane with a hardened finish coat. Because hot water heaters are usually installed in relatively protected areas, the only concern is atmospheric corrosion.

The tank itself is most often made of stainless steel or glass-lined carbon steel, although marine-grade aluminum is sometimes used. Glass-lined tanks are carbon steel with a porcelain coating. Porcelain is very brittle, and cracking and crazing occur over time. Water inevitably

finds its way to the steel substrate. For this reason, glass-lined hot water heaters are usually fitted with a replaceable magnesium sacrificial anode. The anode is frequently an integral part of the hot water discharge fitting. The anode should be checked at least once a year by removing it.

Aside from galvanic corrosion, stainless steels are susceptible to four basic types of corrosion that are significant in this application: pitting, crevice, intergranular, and stress-corrosion cracking. Chloride is the most common agent for initiation of pitting. Freshwater can contain chloride levels as high as 600 ppm, sufficient to cause concern, especially if the water is treated with additional chlorine for purification or flushing. Crevice corrosion can be thought of as a severe form of pitting corrosion, and a well-designed tank will keep crevices to a minimum. Weld decay, a form of intergranular corrosion associated with welds, results from the sensitization developed in the heat-affected zone during welding. An improperly welded tank or the use of improper filler metals or grade of stainless steel can result in susceptibility to crevice corrosion. Stress-corrosion cracking requires residual or applied surface tensile stresses, chlorides, and an electrolyte (water). Most mill products—sheet, plate, pipe, and tubing—contain enough residual tensile stresses from processing to be susceptible without the presence of any external stresses. Cold forming and welding add additional stresses. Laboratory studies have shown that stress-corrosion cracking can occur with chloride concentrations of less than 10 ppm.

Aluminum is sometimes used for both the heating tank and the heat exchanger. The best aluminum is a corrosion-resistant marine grade that is reportedly not as susceptible as stainless steel to leaks at welded seams. Experiential data are lacking, but this is not the material of choice for the top-of-the-line hot water heaters.

Heat exchanger coils should be made of cupronickel. Copper fittings are corrosion resistant and are preferred to galvanized fittings. Copper tubing is frequently used in the hot water circuit and will give good service, keeping in mind problems with erosion-corrosion. Electrical heating elements specifically designed for this application are of tin-plated copper, and they stand up well.

Wastewater Systems. Federal marine sanitation laws require that all boats with installed toilet facilities must also have a marine sanitation device (MSD) that treats and/or stores the waste. The MSDs are Coast Guard-certified types I, II (macerators), and III (holding tanks). The toilet, the chosen MSD, is combined with piping, valves, and perhaps pumps to assemble a sanitation system.

Toilets. There is little to go wrong with a manual marine toilet, as long as it is operated correctly, cared for regularly, and given a periodic rebuild. Keep the pump works lubricated and thus protected from wear and corrosion. Electric macerating toilets are not much more complex than simple manual toilets.

Types I and II MSDs. Where treated discharge is legal, vessels 20 m (65 ft) and under may use either type I or II MSD. Aside from pump impellers, the principal corrosion concern is shaft seals and gaskets damaged by exposure to harsh chemicals. The best preventive procedure is frequent freshwater flushes.

Type III MSD. A type III MSD is a holding tank. Both aluminum and stainless steel have been used for holding tanks. This is not a suitable application for these metals or for any of the common metals, for that matter. Urine is extremely corrosive. It rapidly and aggressively attacks seams, weld laps, and crevices. Typically, metal tanks will begin leaking at the seams and fittings in a year or two. Coatings are not very effective, and repairs are frequent and expensive. The most cost-effective solution for metal holding tank problems is to change them out for a more suitable material. Seamless, thick-walled molded polyethylene is the material of choice.

Vented Loops. When a toilet is installed below the waterline, as it is on most sailboats and in many power boats, there is the risk that water will siphon back into the toilet, perhaps flooding the boat. To prevent this, discharge (and sometimes inlet) hoses lead to and from a U-shaped tube mounted above the waterline at all angles of heel. This device is called a vented loop or siphon break and is available in bronze, Marelon, and plastics. Periodic inspection, disassembly, and cleaning are essential.

Masts, Spars, and Rigging

The mast and its support components—spreaders, stays, shrouds, terminals, toggles, turnbuckles, and chainplates—comprise an integrated, interdependent system that is highly stressed under static conditions and subject to even greater dynamic stresses when sailing. Failure can occur at a number of points in the system, many, or possibly any, of which could bring down the entire rig. The principal components are all susceptible to stress, fatigue, corrosion, and/or rot, and detection of these conditions requires close and regular inspection.

Masts are wood, metal, or composite. Each of these materials presents unique corrosion concerns.

Aluminum spars are generally extruded sections of 6061-T6 (UNS A96061)- or 6063-T6 (UNS A96063)-grade aluminum (Fig. 11). These are excellent corrosion-resistant grades, and properly designed aluminum masts are relatively low-maintenance systems. Problems with aluminum spars are with the fittings rather than the mast extrusion. However, aluminum masts are of relatively thin sections and cannot afford to lose much wall thickness to corrosion without suffering significant strength reduction. They are susceptible to galvanic corrosion, especially with copper, so all copper and copper bearing metals

must be isolated from contact with an aluminum mast.

Both UNS A96061 and A96063 are marine-grade alloys with good resistance to atmospheric corrosion. They quickly develop a protective barrier oxide film such that the corrosion rate declines with time. For the most part, the result is a mild roughening of the surface but no significant thinning of the mast section. The consequences of atmospheric corrosion usually have more to do with appearance than mechanical damage, as long as the protective film remains intact. If the film is continually chafed or abraded away, it loses its protection, and significant loss of metal can occur. Some aluminum spars are anodized, an electrochemical bath process done before any fittings are installed. These spars are highly resistant to corrosion and tend to maintain their finish well. A good paint coating can be attractive, protective, and long-lasting if done properly, but painting aluminum requires special care and preparation.

Welds are the first places to look on an aluminum spar for evidence of corrosion. Poor welds will have rough, sharp edges and crevices where water can collect and cause corrosion. Corroded welds should be redone immediately. Rivets are another place that should be checked regularly. Faulty rivets should be drilled out and replaced with the next-larger size. Anywhere water is allowed to collect and stand against the mast, pitting corrosion can be severe. Compare the depth of corrosion pits with the thickness of the mast at normal openings in the mast. If the corrosive penetration approaches 25% of the wall thickness, or if the damage forms a continuous ring around the mast, serious weakening has occurred, and repair or replacement is essential.

Fig. 11 Typical aluminum mast system

Wood. Most wooden masts are now of hollow-section construction with solid reinforcing blocks where spreaders, tangs, and other components are attached. Sitka spruce is the preferred wood due to its great strength-to-weight ratio. Fastenings in a wooden mast should be of silicon bronze. Mild steel should be avoided because of rusting and deterioration of the wood surrounding the fastening, resulting in a weak and unreliable fastening. Even when galvanized, it is just a matter of time before rusting will occur. Type 316 stainless steel should be used if bronze cannot be used because of galvanic compatibility.

Steel masts are sometimes used in very large sailing vessels, but weight makes steel impractical for most sailboat applications. However, many small commercial boats use steel spars for general lifting or for handling fishing gear. Typically, these are of cold-rolled steel. Almost any low-carbon steel may be used.

With steel spars, any place that water can accumulate is a potential problem area—gaps between adjoining surfaces, pockets, troughs, and corners. All fittings attached to the mast should be continuously welded along their perimeters and the welds ground smooth to avoid water traps and to facilitate painting. It is best if the mast is made air- and watertight, that is, all seams continuously welded and the mast fitted with external halyards and sheaves so that there need be no entry or exit boxes to allow water to get inside. If openings exist through which water can get into the mast, water traps and drains must be provided, and the mast should be painted internally to inhibit corrosion. If electrical wiring is run internally (in polyvinyl chloride tubing), waterproof plugs and connectors or cable gripping wire seals must be used at the entry and exit points. The external surface of the mast must, of course, be painted. Mild steel surfaces subject to wear or abrasion corrode very quickly, which can be dangerous for standing rigging fittings and trawl gear.

Carbon Fiber. Carbon occurs in its natural state as graphite, a highly noble material with a corrosion potential on the order of +0.23 to +0.30 V—at the most noble or cathodic end of the galvanic series. It is highly resistant to atmospheric corrosion. However, the metals typically used in fittings and fastenings—aluminum, at -0.76 to -1.00 V; steel, at -0.60 to -0.71 V; and even bronze, at -0.4 to -0.31 V—are all quite anodic with respect to carbon fiber. Given the necessary electrolyte—salt-water, spray, or dew—the inevitable result is rapid galvanic corrosion of the less noble metal. Titanium, at -0.05 to -0.06 V, and type 316 stainless steel, at 0.00 to -0.10 V, are marginally acceptable. Use of stainless steel fastening galvanic separations in the 200 mV range and an unfavorable cathode-to-anode area ratio are judged based on relative size and duration of localized wetted surfaces. Fastenings should be inspected annually. Alternatively, a fiberglass or epoxy plug for the fastening can be used. Such plugs are often installed by the manufacturer and

can be added for aftermarket fittings. Insulating plugs and pads can be Delrin, Teflon, nylon, Mylar, or polyethylene. The edges between the carbon-fiber spar and the fitting should be sealed with a silicone sealant.

Booms and Spreaders. Booms may be made of the materials from which the masts are made; the differences are in the end fittings. Booms normally have an outhaul sheave at the afterend and a gooseneck fitting at the mast. These are, of course, made of metal—bronze or stainless steel in the case of a wood boom, stainless steel or aluminum in the case of aluminum. Bronze or any copper-base alloy cannot be used on an aluminum spar.

If a spreader fails, the mast has lost the support of the shrouds on that side. If the boat is under sail, the mast and, consequently, the boat and crew are significantly endangered. Damage or corrosion at the spreaders is ranked second only to faulty swage fittings as the primary cause of mast failures. For wood spreaders, fastenings at the spreader roots commonly consist of a stainless steel or bronze plate on the top surface and a matching one on the bottom surface, with through-bolts or clevis pins. These should be thoroughly bedded to prevent moisture intrusion. Concerns about aluminum spreaders are essentially the same as those for aluminum masts: Welds, rivets, screws, and through-bolts should show no signs of corrosion. When inspecting fastenings, inspect for stress cracks around the holes. At winter layup, give the spreader tips a generous squirt of a moisture-displacing anti-corrosion spray.

Mast Step. The heel of the mast and the mast step, whether on deck or on the keel, are highly susceptible to corrosion. In the case of wood masts, anticipate rot, deterioration, and corrosion of fastenings in this area. Also, the heel of the mast works when sailing, so there are problems of abrasion and wear to exacerbate deterioration caused by moisture penetration. In the case of aluminum, steel, and carbon-fiber masts stepped on the keel, there is also the potential for galvanic corrosion of bronze or steel keel bolts and floor fastenings, should they come in contact. Avoiding or insulating such contacts and keeping the bilge dry will help to eliminate this source of corrosive damage. Dissimilar metal fasteners in the mast and step must be isolated or insulated. Protective paint coatings and corrosion-inhibiting lubricants are recommended.

Mast Partners. If the mast is stepped on the keel, the place where the mast passes through the deck is referred to as the partners. This opening is typically greater in diameter than the mast to allow for some adjustment. Often, an aluminum mast will be internally reinforced in the area of the partners and provided with drain holes above the boot. Maintenance and prevention consists of keeping drain holes clear and removing the boot periodically for examination of the mast.

Mast Cap. The mast cap, also called the masthead box, is one of the more important of the mast fittings. Mast caps are often cast aluminum alloy on smaller boats and sometimes galvanized

steel on older boats, but most are fabricated from stainless steel. Concerns are with galvanic corrosion between the cap and its fastenings and the mast. Corrosion is localized and limited to the interface between the two dissimilar metals.

Sail Track. The extruded luff track in aluminum masts normally does not cause serious problems, as long as nylon slides or bolt ropes are used. On wooden masts, there are basically two types of sail track: the luff groove, a slot routed into the afterside of the mast, and the metal slide track. The luff groove has the virtues of simplicity, immunity to corrosion, and virtual trouble-free service, because it only sees the luff rope. The metal slide track of brass, aluminum, and stainless steel is susceptible to corrosion, which can create friction and jam the slides. Nylon slides help a great deal, but lubricating the slides and track with a moisture-displacing corrosion inhibitor is also very helpful.

On a steel mast, a well-bedded wood spacer is mounted on the afterface of the mast, and the sail track is fastened to this spacer, using machine screws tapped into the mast. One must be concerned with the potential for galvanic corrosion.

Fittings and Fastenings. Some spar fittings are cast aluminum—either 356.0 (UNS A03560) for end caps and other light duties, or 535.0 (UNS A05350) for cleats and other load-bearing fittings. Others, particularly tangs, pad eyes, and the like, are of stainless steel. Even bronze fittings, usually in the form of halyard winches, are sometimes attached to aluminum masts. Here again, all metal fittings that are not aluminum must be insulated from the mast, using pads of neoprene, polyvinyl chloride, Delrin, wood, or some other nonconductive material.

Fastenings are normally stainless steel screws or rivets. Galvanic corrosion will inevitably take place but will be limited to the interface between the fastening and the mast. Look for telltale white powdery residue around the fastening. Preventive maintenance for threaded fastenings consists of annual withdrawal, cleaning of the mating surfaces, and coating with a moisture-displacing anticorrosion lubricant. With rivets, corrosion enlarges the hole, and the rivet becomes loose. The fix consists of drilling out the old rivet and replacing it with the next-larger size, using a closed-end (water- and vaportight) rivet with both the rivet body and mandrel metals of aluminum (5052 or 5056), stainless steel, or Monel. Keep an eye out for cracks and pitting corrosion in mast tangs, chainplates, and other fittings subject to stress and vibration. The part should be replaced if any cracks are found.

Masthead electronics failures are usually the result of faulty connections, most often at the bottom of the mast. The connections at the masthead are also vulnerable to moisture penetration, followed by corrosion, signal degradation, poor performance, and ultimately failure. For electronics, the point of greatest susceptibility is the coaxial cable connector, such as the PL-259 type or BNC types. Also, the coaxial cable itself, by virtue of its construction, has a tendency to wick moisture between the sheath

and the tinned-copper braided shield. These connectors have a trouble-free life of approximately three years.

Standing Rigging. There are basically three types of standing rigging in common use: galvanized wire rope, stainless steel wire rope, and rod rigging. Galvanized wire rope is used mostly on commercial vessels for reasons of cost-effectiveness and by traditionalists for authenticity. Stainless wire rope, by far the most popular, is the de facto standard for recreational yachts. Rod rigging is used almost exclusively by high-tech, high-performance sailboats.

Wire rope is made up of multiple strands of thinner wire twisted together into a specific configuration. The most common type for standing rigging is 1 by 19, a central strand with 18 strands of the same gage wire wound around it. Other common types are 7 by 7 and 7 by 19. Because the 1 by 19 is too inflexible to wrap around a thimble or a rigging eye, it requires rigging terminals of another type.

Galvanized and stainless steel wire ropes are both susceptible to several forms of corrosive damage: rusting, pitting, and crevice corrosion. Rod rigging is less susceptible because of the alloy normally used—Nitronic 50—and because rod has a smoother surface and fewer crevices. Both wire and rod are also susceptible to corrosion fatigue and, according to some, stress-corrosion cracking.

The strands at the center of the cables tend to corrode first and most rapidly because of oxygen depletion. The most likely failure point is at the end terminals, but rust and broken strands do occur along the length of the wire rope, especially low on the shrouds and stays. The telltale warning signs are broken strands. Many authorities say that there is no acceptable number of broken strands, and replacement is advised.

Corrosion fatigue can affect the shrouds, stays, and rigging fittings, especially tangs and chainplates. Stress-corrosion cracking as a rigging concern is a bit controversial (Ref 8–13). Failure analysis of riggings is not conclusive, and some controlled experiments on austenitic stainless steel specimens have been unable to replicate stress-corrosion cracking in marine atmospheres. The author's opinion is that stress-corrosion cracking is a possible, even likely, explanation for some otherwise unexplained rig failures. To prevent stress-corrosion cracking, select a metal alloy such as the superaustenitic or 6 Mo (6% Mo) alloys—254 SMO, 20Mo-6, or AL-6XN—or alleviate the cause by reducing residual-stress levels through heat treating, eliminating places where aqueous chlorides can collect or concentrate, lowering the ambient temperature, and applying some form of cathodic protection.

When galvanized wire rope begins to corrode, it rusts, typically in the strands at the core at the lower ends of shrouds. When the rust is very slight, it may be turned end-for-end, getting another season or two out of it. Galvanized wire rope is normally lubricated as part of the manufacturing process, and maintaining the lubrication to help prevent corrosion and reduce wear is

a simple matter once a year with an oil-soaked rag.

When stainless steel wire rope begins to corrode, it develops pitting and crevice corrosion in the strands at the core, not visible in the early stages. Pitting and crevice corrosion in stainless steel wire rope are extremely serious and form the initiation sites for stress-corrosion cracking. Stainless steel grades most commonly used in wire rope are the type 18–8's, primarily types 302 and 304. However, type 316 is the standard high-corrosion-resistance grade that is the recommended grade of the Offshore Racing Council.

Wire rope intended for lifelines and steering cables is frequently coated (sheathed) with nylon or vinyl, sealing in cable lubricants and keeping out dirt and moisture, in order to extend its life by protecting it from abrasion. However, moisture can penetrate and wick up under the sheathing if the sheathing becomes cracked or cut, resulting in pitting, crevice corrosion, and broken strands. This can be a serious failing, because the damage is not visible. The Offshore Racing Council regulations do not permit the use of sheathed wire in lifelines.

Rod Rigging. The alloy of choice for rod rigging is a special grade of stainless steel called Nitronic 50 (UNS S20910). This alloy may be more familiar as Aquamet 22, commonly used in propeller shafts. It is a highly corrosion-resistant material that is affected by corrosion fatigue.

Terminals, Turnbuckles, and Chainplates. The most likely cause of rigging system failures is corrosion-induced failure of a terminal fitting, turnbuckle, chainplate, or their fastenings.

Terminal Fittings. One of the oldest methods still in common use is the clamped eye splice. It is simple, quick, inexpensive, and it holds well. It has the advantage of being open to air circulation and to view and the disadvantage of having lots of cracks and crevices to accumulate and concentrate salt deposits, leading to pitting and crevice corrosion. A more popular current option is the Nicopress or, in the United Kingdom, the Talurit fitting. With this type of fitting, a terminal eye is formed by sliding a double-barreled metal sleeve or ferrule over the standing wire rope, bending the rope around the thimble, and passing its bitter end through the other side of the sleeve, then crimping the sleeve with a special tool. Sleeves are available in copper, tin-plated copper, zinc-plated copper, and aluminum. Coating with a dollop of sealant after crimping will also help keep out moisture.

Swage terminals are probably the most widely used of all wire terminal fittings (Fig. 12a). The swage terminal is a stainless steel fitting consisting of an eye, fork (or clevis), or threaded stud on one end and a sleeve on the other. The sleeve is precisely sized to be tight-fitting for the wire rope. The wire is inserted into the sleeve to the full depth, and the sleeve is put through a set of hydraulic rollers and subjected to tremendous pressure. The result is a cold-worked bond between the sleeve and the rope. These fittings

have far fewer places for moisture and salt to concentrate, but the stresses introduced by cold working the sleeve, together with the salt-laden atmosphere, set up conditions favorable for stress-corrosion cracking failures. Improper swaging is the major reason these terminal fittings have a poor reputation, especially in the tropics. Attempts are made to seal the opening at the top of the swage with all sorts of things: polysulfide sealants, two-part epoxy adhesives, polyurethanes, and so on. The problem is that moisture is sealed in under the sealant unless the sealant is applied when the terminal is new and in a dry atmosphere.

Another class of terminal fitting is a mechanical assembly that relies on compressive forces applied by the assembly process to hold the wire rope in the fitting (Fig. 12b). Mechanical terminal fittings are quite common on yachts, second only to swage fittings. When properly assembled, mechanical terminals have an excellent reputation for durability and reliability. They are not susceptible to stress-corrosion cracking and, if properly assembled, are highly resistant to moisture penetration and salt concentration. This type of terminal is often referred to by the trade name of one of the best-known manufacturers, Norseman or Sta-Lok.

Another wire terminal end fitting is the spelter fitting, which refers to the molten zinc that is used to hold the end of the wire rope in the terminal fitting. The modern version of the

spelter fitting uses fast-setting epoxy in place of the molten zinc.

All of these fittings are continuously exposed to salt-laden moist air, spray, and occasional drenching in saltwater. It is a good idea to seal all openings and crevices on all lower fittings—of any type—with a sealant. However, if the fittings are already in use and have been exposed to salt-laden moisture, the moisture and salt crystals will be sealed in, so thorough flushing and drying before sealing is a must.

Turnbuckles are used to take up slack in the standing rigging. They come in two basic types: open body and closed body. Advocates of closed-body turnbuckles prefer them because they have a tendency to exclude water, and because a grease fitting can be fitted in the barrel and the cavity pumped full of grease periodically to prevent seizing and to inhibit corrosion. Open-body advocates say that this type does not retain water and therefore is less likely to corrode, and they are also easier to inspect. On commercial boats, it is customary to fill the open-body cavity with waterproof grease, wrap the turnbuckle with canvas, and then cover it with a sewn canvas sleeve.

Marine turnbuckles come in four basic materials: galvanized steel, stainless steel, bronze, and a combination of bronze and steel. Galvanized turnbuckles are the most susceptible to corrosion, especially on the threads. Stainless steel does corrode when it is made to stand in oxygen-depleted moisture, which is what happens inside the turnbuckle and around the threads and clevis pins. These are the places where salt crystals concentrate and, given normal loading and some temperature elevation from a tropical sun, the conditions necessary for stress-corrosion cracking are present. Stainless steel is also susceptible to galling. The solution is to keep the thread surfaces clean and well lubricated with a moisture-displacing anticorrosion lubricant. Bronze turnbuckles are resistant to corrosion and galling. There are also stainless-steel-body turnbuckles with bronze threaded inserts and chrome-plated bronze bodies with stainless steel screws. Experience has shown that initial concerns about galvanic reactions between the bronze and the stainless steel were unfounded. This type of turnbuckle has been in wide use for many years with no notable problems. Turnbuckles should receive periodic inspection throughout the sailing season and a thorough examination at least once a year.

Chainplates are the attachment points on the hull for the shrouds and stays. They are typically of steel plate and shaped, formed, and/or welded to the correct angle of alignment with the shroud or stay. Chainplates are under considerable strain, and if they are misaligned, the result is severe working of the fitting and its fastenings, setting up conditions for moisture penetration and several forms of corrosive damage. The more serious failure modes for chainplates are corrosion fatigue and intergranular corrosion (weld decay). Failure usually occurs at the bend or the weld, even though the maximum

stress is considerably less than the yield strength. Look for pitting, crevice corrosion, and tiny cracks in these areas. Lifting or bubbling of paint coatings is another indication of pending trouble.

Running Rigging. The running rigging consists of the various lines that control sails and spars: halyards, sheets, downhauls, outhauls, topping lifts, and so on. These lines are natural fiber, synthetic fiber, wire, or some combination of these. Wire rope used in running-rigging applications is typically 7 by 19. It may be galvanized or stainless steel. Sometimes a rope-to-wire splice is used on halyards to provide a fiber "tail" for ease of handling on the hauling end. Like standing rigging, wire running rigging is vulnerable to saltair and spray penetration into the core, resulting in the same corrosion problems and making the same precautionary measures appropriate. Regular inspection for signs of rust and broken strands is important.

Blocks and Sheaves. Old-fashioned wood-cheek blocks are not used much anymore, except by traditionalists. Modern blocks are lighter and more efficient and have aluminum, stainless, plastic, or composite cheeks. Straps are invariably stainless, although titanium is sometimes used in blocks intended for competitive racing. Corrosive damage to the cheeks and straps may be unsightly but is seldom the cause of block failure. Sheaves are most commonly aluminum for wire rope. Bearings may be of bronze, stainless steel, or, in some cases, an advanced plastic. Bushings may be oil-impregnated bronze or, in the more expensive blocks, an advanced plastic. Aside from aesthetic deterioration to the cheeks and straps, corrosion damage results from saltwater, dirt, grit, and salt crystal intrusion into the axle bearing/bushing assembly, the part of the block that is most vulnerable to corrosion. Sheaves should be inspected at least once a year for surface corrosion and wear.

Corrosion of Metal Artifacts and Works of Art in Museum and Collection Environments

Jerry Podany, Paul Getty Museum

BRIDGES, AUTOMOBILES AND SHIPS have little in common with bronze sculptures, silver commemorative plaques, or lead archaeological artifacts, it would seem, other than that they contain metal. Vast resources are spent worldwide to protect the first group from corrosion, despite their exposure to a wide range of corrosive environments. The second group, by contrast, is assumed to be safely sheltered in the protective enclosures of museums or storage facilities where their long-term preservation is assured. However, artifact or bridge, sculpture or ship, all metal corrodes, and the agents of corrosion can be found everywhere, even within the protective walls of a museum. Indeed, the museum walls themselves may be the source of corrosive agents.

Within such protective environments, surprisingly corrosive microclimates can exist. Corrosive pollutants such as ammonia, formaldehyde, acetaldehyde, formic acid, and acetic acid are often found in higher concentrations indoors than outdoors, inducing an array of chemical, electrochemical, and physical corrosion processes. These processes remind us that while the indoor environment can be less aggressive, it is by no means passive. This situation is often due to the fact that the display materials used in museums and for the buildings themselves have dramatically changed over the last century. Cheaper, reformulated products as well as a dramatic increase in synthetic materials have all introduced greater levels of pollutants, most of which are potentially harmful to collections.

There can be an abundance of corrosive agents within storage cabinets, display cases, and galleries. The materials making up display cases, paint on the walls, or the carpets on the floors may all be the sources of an artifact's demise. Indeed, even the materials that were used in the manufacture, cleaning, or repair of an object can contribute to corrosion. Perhaps slower in pace and smaller in scale but destructive nonetheless, these corrosion processes mimic the more dramatic and extensive processes outdoors. It

should be noted as well, that buried artifacts can suffer from excavation and subsequent transfer to a seemingly more benign environment. See the article "Corrosion of Metal Artifacts in Buried Environments" in this Volume.

Over the centuries, artists and craftsmen have used an impressive array of alloys. Cast bronze portraits, tin plate, stainless steel and aluminum sculpture, silver and gold jewelry, gilded furniture, and iron decorative plaques are joined in this list by paintings on copper and tin and weavings incorporating metallic threads of gold, copper, and silver. Glass vessels and mosaics shimmer with sandwiched layers of gold, silver, and, in more modern times, even aluminum foil between the layers of glass. The variety of metals and their uses for both artistic expression and industrial design are staggering.

The corrosion processes are detailed elsewhere in this Volume. This article points to the most common of the processes found indoors and focuses on the sources of corrosion in what otherwise would be considered the protective environment of museums and historic collections.

Common Corrosion Processes

The processes and agents of corrosion, like the rusting of iron in the presence of water and oxygen, are just as likely in the museum environment as elsewhere.

Humidity. High relative humidity (RH) is, of course, a leading concern in the preservation of any work of art or historical artifact. Museums or storage facilities lacking adequate climate control in some areas can experience high RH indoors. Collections in tropical zones are particularly challenged, but those in more moderate climates can face 85 to 90% RH for prolonged periods during the summer months.

High RH encourages corrosion in a number of ways. For example, archaeological iron from marine excavations will often have a variety of soluble salts embedded in the corrosion layers.

When the humidity is sufficiently high, these salts will attract moisture and dissolve, forming an electrolyte. Iron in this condition exhibits brown droplets of moisture on its surface, giving it the name "sweating" or "weeping" iron.

Temperature fluctuations affect RH. While it is impractical to cool exhibition areas below the comfort level of museum visitors, unnecessary heating of metal objects and their environment by radiant energy can encourage corrosion, because an upward shift in temperature may mean an increase in available water vapor and in the reaction rate. For example, lighting sources within display cases can dramatically increase the interior temperature of the case. The heated air will retain more water vapor. When the lights are turned off at the end of the day, the temperature drops, and the RH rises within the case. As a result, the environment may reach the equilibrium RH of some salts. An electrolyte may form, even in the absence of visible condensation, and corrosion is initiated.

These conditions are relatively straightforward to manage in museums and collections through the strict control of RH by building-wide environmental systems or localized microclimate cases and climate-controlled storage cabinets. Simple preventive efforts may include coatings that protect the metal surface by being somewhat impermeable to moisture. Although direct intervention remains an option, modern conservation practice encourages the control of the environment rather than the imposition of any direct treatment, because such treatments inevitably alter the material nature of the object and are not always effective.

Relative humidity below 40% is an effective way of controlling bronze disease present on archaeological copper alloys that contain layers of reactive cuprous chloride. Bronze disease is essentially a process by which cuprous chloride, nantokite (CuCl), converts to one of the trihydroxychlorides (cupric chloride, CuCl_2 ; atacamite, $\text{Cu}_2(\text{OH})_3\text{Cl}$; or its dimorph, paratacamite). A dry environment is preferred to

direct treatments for bronze disease, such as the application of a water or alcohol solution of benzotriazole, which forms a complex with the copper chlorides but is not always effective over the long term. For these same reasons, the use of effective sulfide scavengers (zinc oxide pellets, for example) and the retention of low RH levels are preferred to the repeated removal of silver tarnish through chemical strippers or abrasive polishes, because both have an irreversible effect on the original material and do nothing to prevent further corrosion.

Temperature. In addition to affecting RH and directly affecting the corrosion kinetics, a temperature increase can alter the environment by accelerating a variety of chemical processes. An example described at the *Indoor Air Quality in Museums and Archives* Web site (Ref 1) describes a polyvinyl chloride lamp fixture within a museum showcase that may well have released chlorine to form hydrochloric acid vapor into the showcase due to the heat of a light bulb in the case.

Light. One perhaps surprising source of corrosion is radiant energy. In the early 1990s, the role of light in the corrosion of metals was found to be more significant under certain conditions and in the presence of certain pollutant gases than previously assumed, especially in accelerating the corrosion of silver. Oddy and Bradley noted (Ref 2) that when silver coins with a dark-purple patina (typical of silver chloride) were exhibited, their upward-facing surfaces became hazy with a milky-white appearance. By comparison, the opposite sides remained unchanged. Scanning electron microscopy analysis revealed the milky haze to be composed of a white powder that was almost pure silver. Later measurements showed that the light intensity in the location of the exhibition case was as high as 960 lux, with an ultraviolet content of 70 $\mu\text{W}/\text{lumen}$. The researchers postulated that such energy levels were sufficient to reduce the silver chloride on the surface of the coins to pure silver.

Pollutants

The list of aggressive pollutants and their sources in museums and collections is long. Polluting gases such as hydrogen chloride (HCl), ammonia (NH_3), formaldehyde (HCHO), sulfur dioxide (SO_2), hydrogen sulfide (H_2S), carbonyl sulfide (COS), carbon dioxide (CO_2), nitrogen oxides (such as nitrogen dioxide, NO_2), and ozone (O_3) may come into the museum environment from outdoors and be absorbed or adsorbed by metallic surfaces or existing corrosion layers. Once in place, they initiate corrosive processes in the presence of water. For example, adsorbed SO_2 collects sufficient water at 75% RH to undergo a catalytic oxidation to sulfuric acid. Nitrogen oxide pollutants (NO and NO_x) that come predominantly from automobile exhaust or the decomposition of materials are of equal concern, because nitrogen oxides can

convert in the presence of water to aggressive acids:

which then convert to HNO_3 (nitric acid).

Pollutants do not act independently, and their interactions can be quite destructive, although all the interactions with each other and with metal substrates are yet fully understood. Research shows that the reaction of SO_2 with NO_2 on a metal surface can produce nitrous acid (Ref 3):

The combination of SO_2 and NO_2 can have a corrosive effect on metal a full order of magnitude greater than the effect of SO_2 alone and silver sulfidation caused by hydrogen sulfide increases when NO_2 and ozone are present (Ref 4). Additionally, the combination of NO_2 , SO_2 , and ozone will tend to inhibit the formation of a protective, oxide layer and encourage the formation of a sulfate layer, which is much more damaging to the metal surface.

Acidic deposition can infiltrate the porous structures of patinas (Ref 5). In museums, although certainly far less dramatic than outdoors, the effect can be significant, because the visual appearance of the patina may be altered, and the analytical/archaeometric value of the patina makeup and structure may be compromised.

While ozone and nitrogen dioxides can be controlled in museum environments through filtration (using activated charcoal, for example), nitrogen monoxide cannot be removed without great difficulty. The presence of nitrogen monoxide is not a major concern, however, unless ozone is present, because ozone will combine with nitrogen monoxide and water to form nitric acid.

Soluble salts that may be present on the metallic surface can act in combination with water as electrolytes. Chlorides, for example, can be present as a residue of previous treatments or repairs. Sodium chloride, which can accelerate the corrosion of metals (especially copper and silver), is often found on archaeological objects excavated from marine burials or from terrestrial sites where the soil includes high concentrations of chlorides. If a collection is housed within a few miles of an oceanfront, salt can also enter as airborne particulates approximately 2 μm (0.08 mils) or larger.

Beyond direct soiling that requires repeated cleaning of the metallic surface, particulates affect corrosion processes due to their hygroscopic, acidic, or alkaline nature. These include sodium chloride (NaCl), ammonium sulfate ($(\text{NH}_4)_2\text{SO}_4$ and $(\text{NH}_4)\text{HSO}_4$), ammonium chloride ($(\text{NH}_4)\text{Cl}$), and sodium sulfate (Na_2SO_4). A study of relatively polluted urban locations (Ref 6) found such corrosive particulates (especially those less than 0.1 μm , or 0.004 mils) to be present in some museums and historical collections at levels almost as high as in the immediate outdoor environment. While

most particulates can be removed by standard filtration systems widely available to museums, some are too small or enter the building through uncontrolled openings, such as windows and doors. These particulates (or aerosols) can be rich in nitrates and sulfates, such as those that are formed by the atmospheric condensation of SO_2 and nitrogen oxides, and as such pose significant corrosion risks to collections. This situation can also be true for a variety of acidic particulates produced in photochemical smog, because anthropogenic particulates of 1 μm (0.04 mils) or smaller are difficult for most general filtration systems to remove. While some of these agents may not corrode metal directly, they can play a catalytic role or may degrade other materials that in turn produce corrosive agents. Additionally, some metals (notably copper, zinc, nickel, and alloys containing these metals) are particularly sensitive to aerosol particulates, such as ammonium sulfate and SO_2 , in combination with oxidants, such as NO_2 and ozone (Ref 4).

To the list of corrosive agents must be added the one that walks into the collection on two legs: the visitor. Visitors not only bring considerable amounts of corrosive agents into the museum environment (detritus, fumes from clothing, and human bioeffluent) but also may contribute more directly to the corrosion of the object by improper handling, resulting in physical wear and residues of salts, acids, and oils deposited on the metal by contact with skin.

The Museum as a Source of Corrosion

If one thinks of a museum, gallery, storeroom, or cabinet as an envelope, a number of different corrosion scenarios can be considered. For example, the envelope may not be sufficiently sealed or filtered and may allow outside conditions to influence the interior environment.

Sources for corrosion may come from the interior of the envelope. In this context, even quite small amounts of some pollutants can initiate significant reactions, especially in confined spaces with little or no regular air exchange. In many instances, works of art and artifacts are displayed or stored in exactly such confined spaces (either small storerooms, sealed storage containers, or closed display cases), where deleterious gases and vapors from inappropriate construction or display materials increase to significant concentrations. In wooden storage cabinets, the ratio of wood surface (which may be emitting harmful vapors) to the interior volume is such that even low emission rates lead to dangerous levels of pollutants. The sources for such pollutants in storage facilities and display environments are surprisingly numerous. The processes for manufacturing fabrics used for furniture upholstery, wall coverings, or to cover the interior of display cases may include a host of harmful chemicals, such as reduced sulfides and formaldehyde, that

eventually emit gas, either through degradation of the fabric or dye, or because they are present in excess amounts on the fabric itself. Flame retardants, fabric finishes (a formaldehyde-based process that gives us the convenience of permanent press), and water repellents also may emit gases. The effect of such corrosive agents is readily observable. Nails and screws in contact with some fabrics corrode at their contact points after only a few months of exposure (Ref 7). The rapid corrosion of a steel artifact in contact with a dyed yellow fabric was attributed to the inclusion of a halide salt in the dye (Ref 8).

Example 1: Tarnish of Hellenistic Silver Bowls by Use of Sulfur-Laden Velvet. In the mid-1970s, a collection of Hellenistic silver bowls at the J. Paul Getty Museum in California (Fig. 1) was placed in a relatively well-sealed exhibition case that was lined with velvet. Within one month, the surfaces of the bowls began to tarnish noticeably. The case was redesigned, and a more suitable fabric, one not laden with sulfur, was used. Specifically because of such problems, exhibition materials used at the Getty Museum have been regularly tested since 1985 for their potential to damage objects by contact or by proximity.

Plastic and Wood

Plastic products are ubiquitous. Polymers containing hydrolyzable groups such as esters, amides, acetals, and certain ketones can deteriorate and emit by-products such as acetic,

sulfuric, formic, and nitric acid, which are harmful to metals. Added opacifiers, plasticizers, fungicides, stabilizers, or excesses of initiators or catalysts may also be a source of corrosion. Polyvinyl-chloride-based products degrade and emit hydrochloric acid through a reaction of the emitted chlorine with water vapor. Some clear plastic sleeves or envelopes commonly used for storing coins provide an example of this problem. Additionally, bacteria can attack some types of vinyl in humid conditions. The result of this attack can be the release of acids that in turn attack coins.

Most wood or wood-based products emit organic acids (formic and acetic acid) that can readily affect many metals, most notably lead. Among the woods most likely to release harmful vapors are oak, Douglas fir, birch, sweet chestnut, and western red cedar. Composite wood products such as plywood, chipboard, and particleboard (particularly if they incorporate urea-formaldehyde adhesives that are ubiquitous in new construction) emit both acetic acid and formaldehyde (and, as a result, formic acid). Kiln-dried woods and those treated to prevent susceptibility to rot are likely to cause greater corrosion of metals than untreated and air-dried woods (Ref 9).

Sulfur

Recently, the most problematic pollutant to attack metals within the museum and collection environments has been sulfur, particularly

hydrogen sulfide and carbonyl sulfide. While there has been a large reduction in the problems caused by the burning of sulfur-laden coal and by-products from refineries, which were major contributors to pollution problems of European urban centers during the late 19th and early 20th centuries, some countries still suffer from the effects of this pollutant. Because only minute amounts of sulfur can cause significant visual and physical effects on metal surfaces (particularly silver), sulfur is a major concern for collections. In the past, hydrogen sulfide was considered the most reactive and problematic of sulfur compounds. However, carbonyl sulfide is the most concentrated naturally occurring sulfide in the atmosphere and is equally aggressive.

The sources of sulfur within museums include vulcanized rubber in floor mats and carpet backing, and chemicals used in the various stages of drying and finishing textiles, especially felts and velvets. Wool fabrics not only contain sulfur but also can absorb large amounts that can later be released when the environment is favorable or when the wool ages.

Example 2: Silver Sulfide Dendrites Growing on a Greco-Roman Silver Bowl. Rubber floor mats installed in the 1930s at the Walters Art Museum in Baltimore were meant to protect the objects from breaking should they fall. Sulfurous gases emitted from the mats eventually affected some of the metal artifacts in the storeroom. The objects were undisturbed for a long period of time (many years), and this may have allowed for the dendritic formation of the silver sulfide crystals (Fig. 2). The Walters Art

(a)

(b)

Fig. 1 An exhibition case of Hellenistic silver vessels at the Getty Museum in the late 1970s. (a) Red velvet lines the case walls. (b) One of the ancient Hellenistic silver bowls showing significant tarnish due to sulfur from the red velvet. Tarnish began to appear on the surface of the silver within one month of the objects being placed in the exhibition case. Courtesy of J. Podany, 1979.

Museum now has very rigorous and effective storage policies and methodologies. All metal objects are stored in a special metal storage vault with low RH, and pollutant scavengers are included to give additional protection to vulnerable objects.

Sulfurous gases can also be released by modeling clays, protein-based glues, and objects that have been repaired with elemental rolled sulfur (resolidified sulfur). Recipes found in old repair and mending manuals called for sulfur in numerous mixtures of fixing cements and glues (Ref 10, 11). Elemental sulfur, sometimes mixed with sand or iron fillings, was often used for fixing iron pins into stone for repair of sculpture or architectural elements. The sulfur was melted and poured into the hole accommodating the pin. Because the sulfur remained rather soft and rubbery until it fully solidified, it gave sufficient time to make adjustments to the pin and the joint. Because many types of repairs to numerous materials were made with elemental sulfur, these have become possible sources of corrosion.

In polluted urban atmospheres, SO_2 can be absorbed by oxides on the metal surface or dissolved in the water film on the surface of metal (Ref 12). It then combines with hydrogen peroxide or ozone to form sulfuric acid that dissolves the protective oxide on the metal, potentially forming oxide-free or less protective anodic (electron-producing) areas adjacent to cathodic (electron-consuming) areas still protected by oxides. The deposition and formation of sulfuric acid in water films on aluminum surfaces has been shown to be a significant cause of corrosion problems in both urban and industrial atmospheres through the dissolution of the oxide film and then the further oxidation of the exposed metal (Ref 13). One must assume that, given high humidity and the presence of sulfuric acid in storerooms or display areas, similar processes occur, albeit slower. Sulfuric acid can initiate the production of salts, such as ammonium sulfate, that attract moisture and function as electrolytes.

A direct role for SO_2 is proposed for local dezincification of brass (Ref 3). Sulfur dioxide reacts with the zinc content of the object, leaving traces of zinc sulfite that rapidly oxidize to zinc sulfate on the surface. This sulfate is highly deliquescent and causes local areas of condensation, even at moderate RH. The zinc sulfate solution thus formed dissolves more SO_2 that in turn oxidizes to sulfur trioxide. An increasingly concentrated solution of sulfuric acid then dissolves more of the copper-zinc alloy, resulting in the production of a mixed copper-zinc basic sulfate.

The effect of sulfur in museum collections has garnered a great deal of attention and research aimed at identifying the corrosion products and their sources. In 1979, visually disfiguring black spots on bronzes in a collection were reported and identified as copper sulfide (Ref 14). The researcher reportedly was successful at culturing bacteria from samples of the corrosion and went on to suggest that the source of the disfiguring corrosion may have been biological. It has since

been proven, however, that these areas of corrosion, identified as covellite (CuS), are due to the presence of sulfur in the form of hydrogen sulfide, carbonyl sulfide, and similar pollutants in the air.

Example 3: Copper Sulfide Corrosion ("the Brown Fuzzies") on Copper Alloy Artifacts. In the late 1980s, the museum staff of the Oriental Institute in Chicago noticed a dark-brown, almost velvetlike growth on all of the copper alloy objects within a single display case (Fig. 3). The artifacts, which ranged in style and function, had apparently been mechanically and/or chemically cleaned at an earlier date. Since this incident, the same types of growths have been noticed on copper alloy objects on display in other galleries and in various storage cabinets. Taken at face value, this problem would seem to be a building-wide occurrence and not tied to a specific location.

The largest growths appear cauliflower-like and extend farthest from the surface of the object. Those closest to the surface (at low magnification) seem to have a dendritic structure. Analyses of the corrosion products identified them as djurleite (a copper sulfide, $\text{Cu}_{31}\text{S}_{16}$), although additional minor phases cannot be ruled out. Remedial measures have included examining all materials within the exhibition and storage environments and replacing all that may have been emitting harmful vapors.

Corrosion from Carbonyl Compounds

The organic acids produced from carbonyl compounds present in the environment can dissolve metal salts and catalyze corrosion processes. In high-humidity conditions, small amounts of volatile ester solvents, such as those retained in paint films or on the surface of metal objects, can hydrolyze and release corrosive lower fatty acids. Drying oil, semidrying oil paints, or paints containing esters of volatile

acids are potential sources of corrosive vapors (Ref 15).

Although damage to artifacts was first reported in the late 19th century (Ref 16), it was only in the middle decades of the 20th century that in-depth scientific studies of the effects of these compounds on metal artifacts began to occur (Ref 17). There are still some aspects of the interaction between carbonyl compounds and artifacts or art works, however, that are not well understood.

Enclosed storage and display environments can include low-molecular-weight esters that initiate corrosion by hydrolyzing into their constituents of alcohol and acid (the acid being

the corrosive agent). Their total effect remains less significant, however, than the effects of simple organic acids and aldehydes released from wood, wood products, and a wide variety of commercial synthetic products, such as urea-formaldehyde-containing adhesives, varnishes, paints, composites, and fabrics. Upon degradation, cellulose acetate, for example, can release acetic acid. Degraded cellulose nitrate can release nitric acid.

The organic carbonyl compounds most commonly found in collections are:

- **Acetic acid:** Often the most prevalent pollutant in wooden enclosures such as storage boxes, cabinets, or display cases
- **Acetaldehyde:** A product of incomplete combustion from cigarettes and fireplaces. It is in building products such as polyurethane foam, adhesives, coatings, and inks.
- **Formic acid:** Found in wooden enclosures, especially oak, and in glue
- **Formaldehyde:** Also commonly found in high concentrations within wooden enclosures

These carbonyl compounds can also be found in the outdoor environment of many urban areas. Reported levels in Southern California in a 1983 study were 1 to 29 ppb of formaldehyde, 1 to 13 ppb acetaldehyde, 1 to 8 ppb formic acid, and 2 to 10 ppb acetic acid (Ref 18). It is likely that these levels of formaldehyde and acetyl aldehyde will increase, particularly if the consumption of ethanol-based fuels in urban environments increases. These pollutants often find their way into collection environments. However, major sources of these compounds already exist in the indoor environment.

The pronounced effects of carbonyl compounds on lead were among the first studied. The principal corrosion products of lead found in museum collections are lead formate ($\text{Pb}(\text{COOH})_2$), lead acetate ($\text{Pb}(\text{CH}_3\text{CO})_2$), and basic lead carbonate (2PbCO_3). Lead oxide, which readily forms and is more or less protective, will alter to lead carbonate in the presence of organic acids. Lead is more resistant to corrosion when alloyed with as little as 1.5% Sn (Ref 19). Pewter, for example, is often unaffected by conditions that would rapidly corrode objects manufactured of purer lead. The decorative inlays on a number of 19th century Japanese lacquered wooden artifacts experienced a wide range of corrosion damage, based on the percentage of tin alloyed with the lead (which was the predominant metal, in most cases) (Ref 20). The pure-lead inlays showed corrosion so severe that the metal inlays were all but consumed, while lead-tin alloys of up to 80% Sn fared better, some being completely unaffected by the organic acids present in the storage environment. Trace elements in the metal inlays affected the degree of corrosion. Iron and zinc, for example, increased the corrosion damage, while tin, copper, silver, and gold improved the corrosion resistance of the inlay. The corrosion products reported were predominantly lead carbonate with minor

amounts of lead formate. This led the researchers to conclude that the corrosion was due to an alteration of the lead oxide by formic acid being released within the storage environment over a period of some 60 years.

Example 4: Corrosion of a Sculpture Made with Incompatible Materials. On occasion, materials used by artists and craftsmen are incompatible. Some materials used for artistic expression may eventually degrade and emit harmful substances that corrode adjacent metal parts of the work of art. Such was the instance when the nitrocellulose segments of an Antoine Pevsner sculpture at the Museum of Modern Art in New York began to degrade and cause the corrosion of those parts of the sculpture made of copper alloy (Fig. 4).

Acetic Acid. The effects of oak planks on lead roofing in the outdoor environment were already being commented on in the 18th century (Ref 21). Today, we understand the mechanism by which acetic acid, evolving from the oak planks, corroded the lead and produced lead acetate ($\text{Pb}(\text{CH}_3\text{CO})_2$). While one may suspect that such corrosion is only likely outdoors, it is, in fact, also possible within the indoor environments of museums and collections. Acetic acid is released by the hydrolysis of acetyl groups (esters) in the hemicellulose of wood. The rate and amount of this release is dependent on a number of factors, including the ambient RH, temperature, and concentration of esters in the wood. For example, the proportion of acetyl groups giving rise to acetic acid is greater in hardwoods (3 to 5% by weight of the wood) as compared to softwoods (1 to 2% by weight). In many woods, much of the acid content is volatile. Over 90% of the total acid in oak and Douglas fir, the majority of which is acetic acid, is volatile (Ref 22). Corrosion effects should not be surprising when one considers the efficiency by which acetic acid catalyzes the conversion of lead (via its oxide) to the basic carbonate, which was, in fact, the basis for the Dutch process of making lead white pigment. Effects of acetic acid also include the considerable costs faced by commercial wood mills and processing plants due to the corrosion of cutting blades and the corrosion of aluminum coils in dehumidifiers (dryers) used in wood-processing plants.

Wood products have been treated with acetic anhydride to enhance dimensional stability while maintaining other desirable properties. These treated products can release acetic acid. The use of acetylation as an industrial process has been slow to catch on, however, partially due to corrosion of metal fixtures and the entrapment of acetic acid in the wood (Ref 23, 24).

Wood is not the only source of acetic acid in museums and collections. Certain silicone sealants, in which acetic acid is incorporated, can be problematic. Other synthetic products, such as cellulose acetate, release acetic acid as they degrade. Acrylic-based paints often incorporate cellosolve acetate (2-ethoxy ethyl acetate) as a carrier solvent that acts as a source of acetic acid, although the hydrolyzation is slow. The

degradation of widely available polyvinyl acetate adhesives, often used in the construction of furniture and exhibit fixtures, is also a source of acetic acid. Beyond the more common

release of nitric acid, nitrocellulose-based paints and lacquers can also release acetic acid, which is derived from esters in the paint. Some paints based on drying or semi-drying oils can lose as much as 0.0025 wt% of the paint film per day for some time (Ref 15).

The prevalence of acetic acid in collection environments is so problematic that Ref 9 placed acetic acid in the same corrosive category as SO_2 . Significant corrosion occurred at 0.5 ppm concentrations with an ambient RH as low as 70%. Other researchers have found acetic acid active at much lower concentrations. One researcher reported that ancient bronzes corroded relatively rapidly in environments with concentrations of 0.14 ppm (Ref 25). He identified a number of corrosion products on bronze objects stored in wood cabinets, including crystalline and powdery white efflorescence associated with the initial light-blue corrosion products on the surface of the bronzes. This was identified as sodium acetate trihydrate ($\text{NaCH}_3\text{COO} \cdot 3\text{H}_2\text{O}$). The formation of this product does not directly involve components of the metal alloy itself but can be disfiguring nonetheless.

It should be noted that the corrosion potential of low concentrations of acetic acid (as well as other corrosive agents) is dramatically enhanced by a rise in RH. While corrosion of lead by acetic acid was found in concentrations above 0.1 ppmv (volume) at 54% RH (Ref 26) and for copper at 50 ppmv (Ref 27), others report acetate corrosion products on copper alloy artifacts housed in storage cabinets where acetic acid was present in concentrations as low as 400 to 500 ppb but where the RH regularly rose to 85% (Ref 28). It was noted that acetic acid can be adsorbed on the surface of metal objects and can thus collect in one environment but react in another if the humidity levels are sufficient.

In the case of lead, acetic acid plays a major corrosive role, far more than formic acid. However, Tétrault et al. have recently shown that in the presence of formic acid, the ability of acetic acid to corrode lead is significantly inhibited, because the corrosion layer is altered and can become increasingly protective (Ref 26).

One process by which acetic acid continues to corrode lead involves acetic acid (CH_3COOH) vapors finding their way into the cracks and fissures of the lead carbonate corrosion product. The resulting lead acetate ($\text{Pb}(\text{CH}_3\text{COO})_2$) acts as an electrolyte, promoting more corrosion of the metallic lead and formation of additional lead carbonate.

At the tips of the cracks, corrosion occurs by the following process:

New acetic acid is then formed by:

The $\text{Pb}_3(\text{OH})_2(\text{CO}_3)_2$ is hydrocerrusite.

Example 5: Corrosion of Two Chinese Artifacts Possibly Caused by Exposure to Exhibition Case Materials. A Shang dynasty finial (1300 to 1050 B.C.E.) and an Eastern Zhou dynasty ding vessel (500 to 400 B.C.E.) exhibited bright blue corrosion areas while on exhibit at the Asian Art Museum in San Francisco (Fig. 5). Although the exact cause of the corrosion remains unclear, the combination of exhibition case materials, such as wood, fabric, and adhesive, is suspected. All exhibition case materials in the museum have since been changed, and any materials used near art objects must now be tested for corrosive agents. Since that policy has been in place, no similar corrosion problems have been observed.

Example 6: Corrosion of a Japanese Tsuba Stored Near Wooden Boxes. Wood can emit harmful vapors from its structure and from treatments it has received. The vapors, which are often organic acids, can have a significant impact on the preservation of the object. An iron tsuba with inlays of gold, copper, lead, and the traditional Japanese alloys shibuichi (an alloy of silver and copper, often in a ratio of 3 to 1, but recipes are widely diverse) and shakudo (an alloy of copper and 2 to 7% Au) had been stored in the proximity of wooden boxes at the Walters Art Museum in Baltimore and was found to have developed a disfiguring corrosion on its surface (Fig. 6). It was assumed by the conservator who treated the object that the wooden boxes were the source of the organic acids that caused the corrosion. Upon discovery of the condition of the object, it was relocated to a metal storage cabinet coated with baked enamel. The museum now uses Pacific Silvercloth (Wamsutta Industrial Division) over the tsubas, with acid-free tissue between the metal and the cloth (Ref 29). The acid-free tissue was introduced between the object and the silver cloth as a barrier, because the conservator was concerned that silver salts contained in the cloth may adversely affect the copper of the object. The RH within the storage unit is now kept low. Clean lead test coupons have been introduced into the storage environment for several years (starting in 2001), and no corrosion has been observed on the coupon or on the object.

Formaldehyde. Our modern environment is all but permeated with formaldehyde. Worldwide, more than 10 million metric tons are produced annually (Ref 30) for use in a widening array of commercial products. This is an alarming amount, given that concentrations of less than 100 ppb have been shown to cause eye and throat irritation as well as chronic respiratory and allergy problems (Ref 31). With respect to metal corrosion, past research has suggested that concentrations of 0.03 ppm in the atmosphere can initiate corrosion of some metal objects, most specifically lead (Ref 32). Recent studies, however, suggest that formaldehyde has no significant effect on lead or copper (Ref 26). By contrast, the oxidation product of formaldehyde, formic acid, poses a serious problem by corroding lead and copper when the acid is

present at 2 ppmv in RH as low as 54%. Corrosive concentrations can be even lower when humidity is higher. For example, 0.4 ppmv of formic acid can initiate corrosion at 75% RH. The reactivity of formic acid may, however, be reduced significantly after the first layer of corrosion product is formed, because that layer can be somewhat protective.

Sources of formaldehyde in the collection environment include urea-formaldehyde insulation,

(a)

chipboard, and urea-formaldehyde adhesives used in construction. While formaldehyde forms durable polymers when combined with phenol and amines, the addition of urea also produces methylol urea compounds. As a result, urea formaldehyde produces ten times more formaldehyde emission than phenol formaldehyde.

Formaldehyde can be in the carpets or tile covering the floor, the plastic containers holding the works of art in storage, or the paints on the gallery wall or display case interior, particularly if the paint is a latex (containing azoni-adamantane chlorides, oxazolidines, and triazines) or an alkyd paint. Foam rubber, fabrics, and fabric finishes (such as flame retardants, or the size often given to yarn in order to reduce dust in the mill during the weaving process) also contribute formaldehyde. A more recent source has been insufficient baking of solvent-based enamel paints used to coat metal storage cabinets. Such cabinets are commonly preferred in museums and historic collections, because wood cabinets and shelves give off gas acetic acid and produce formaldehyde via the degradation of the wood lignin. Formaldehyde is also a by-product of gas and solid fuel combustion as well as cigarette smoke.

Excess formaldehyde is used to speed up the manufacturing of plastics by inducing rapid cross linking of the polymer. Such excess, combined with the emission due to the breakdown of the resins (often through hydrolysis), provides a significant amount of formaldehyde to react with works of art. Formaldehyde is also formed by a reaction of ozone and terpene hydrocarbons present in new constructions (Ref 31).

The formaldehyde released from these products and reactions can produce a number of destructive processes that become especially serious at elevated temperatures. An increase in temperature of 5 to 6 °C (9 to 11 °F) can double the formaldehyde gas concentration in some instances, as can an increase in RH from 30 to 70%. If both temperature and RH increase, the concentration of gas can increase by five times the initial amount. One must also keep in mind that formaldehyde can be released for an extended period of time. It is reported (Ref 33) that a newly constructed house will emit formaldehyde at a fairly steady rate for up to 9 months, and one can assume this would also be true of new construction within a museum. Although formaldehyde itself can catalyze the corrosion process, it is less active in this way than acetic or formic acid. However, formaldehyde can be oxidized in air by peroxides or ultraviolet radiation to formic acid, which is more corrosive.

Past Treatments

Restoration or conservation treatments meant to preserve objects may, if improperly carried out, be the source of significant corrosion. For example, the common use of chemical dips or cleaning polishes (which can contain acids and/or ammonia) can be quite corrosive to silver. Coatings such as linseed oil, dammar varnish, or shellac (often used in the past to protect objects from humidity) age, oxidize, and crack, exposing the previously protected metal surface. These

cracks, where fresh metal is exposed, can act anodically to cause corrosion. Likewise, if the coating is not applied properly and evenly over the surface, the uncoated areas of the object can act anodically to the coated cathodic areas. Scratches and chips in the coating behave the same way. Recent studies on the destructive effects of filar corrosion of aluminum and magnesium alloys used for contemporary sculpture (akin to that occurring on aircraft) provide general examples of this process (Ref 34). Neat's-foot oil, linseed oils, and shellac used as protective coatings provide free fatty acids or dicarboxylic acids that form metal soaps with, for example, copper and lead (Ref 35). These copper soaps are especially unstable and promote corrosion of copper and its alloys (Ref 3). In one example, metal soaps formed on a brass wire wound around the socket of an African spear that was coated with animal fat (Ref 36). Paintings on copper that incorporate drying oils, and bronzes that have been coated with drying oils have shown the presence of copper soaps on their surface or within the layers of their structure. Reference 37 states that fatty acids can readily evaporate from oil paint films (palmitic acid evaporating more rapidly than stearic). There are many different fatty acids found in drying oils, especially within the modified oils produced in the last half-century. The four predominant fatty acids, however, are two saturated (palmitic and stearic) acids and two unsaturated (oleic and linoleic) acids. Copper, lead, and zinc palmitate and stearate are most often found as the corrosion products. Palmitic acid released by leather, for example, reacts readily with zinc to form an amorphous precipitate. For this reason, brass attachments, such as studs or clasps, on historic leather jackets, boots, or saddles are often found with a green corrosion product covering them, particularly when the object has been stored in a closed and somewhat humid environment.

It has been pointed out (Ref 38) that oils and fats that cause this type of corrosion on bronzes (as well as on zinc and lead) have three ester linkages that can be hydrolyzed (the addition of water across the bond) to produce free fatty acids that can attack metals, as shown in Fig. 7.

Residues of past cleaning, repair, or restoration efforts can also be sources of corrosive agents. Chlorides remaining from fluxes used for solder repairs are an example. More recently (Ref 28), the presence of sodium-copper carbonate acetate ($\text{NaCu}(\text{CO}_3)(\text{CH}_3\text{COO})$) on copper artifacts in storage at the Athenian Agora site was reported. Some of the sodium compounds formed from such treatments (such as chalconatronate) will readily absorb acetic acid (often from the storage environment) and form sodium-copper carbonate acetate products. When such acetate compounds deliquesce, the resulting salt solution wicks into the pores of the existing corrosion products and into the void or cracks of the metal to cause further corrosion. A strong case was made for the source of the sodium

Fig. 6 Japanese tsuba from the Edo/Meiji period with corrosion (arrow) caused by proximity of wood. Original magnification 6×. Courtesy of Terry Drayman-Weisser.

being from previous treatments of the bronzes involving sodium sesquicarbonate, commonly used in the past to stabilize chloride-containing archaeological bronze artifacts. The use of Calgon (Reckitt Benckiser) (previously composed of sodium hexametaphosphate) or the use of sodium hydroxide with Rochelle salts (sodium-potassium tartarate) are also both possible sources of the sodium, because both have been used for cleaning bronze surfaces and sometimes are used with alternating treatments of acetic acid. Patination processes often include ammonia and sodium compounds and involve fuming

the object in acetic acid. They may also include a wide range of acetate, chloride, and sulfide compounds (Ref 39).

Example 7: The Corrosion of Copper Alloy Tacks on a Gourd Box from Zaire. Some objects may combine copper alloy elements with a variety of oils and fats applied to the object during manufacture or for restorative or ceremonial purposes. These oils or fats interact with the copper to cause significant corrosion. In this instance, a late-19th century gourd box in the collection of the University of Pennsylvania Museum of Archaeology and Anthropology in Philadelphia showed considerable corrosion of the copper alloy (probably brass) tacks due to the presence of oil (Fig. 8). The corrosion was determined to be either a copper oleate or a copper stearate or a mixture of the two. The corrosion was mechanically cleaned away and the oil on the surface of the object reduced by solvent cleaning.

Fig. 7 The attack on bronzes by oils and fats. (a) Fats with three ester linkages are hydrolyzed, producing free fatty acids. R_1 , R_2 , and R_3 are long hydrocarbon chains, typically containing 12, 14, 16, 18, or 20 carbon atoms. (b) The free fatty acids attack copper in the presence of water and oxygen, and a fatty-acid salt is formed.

Preservation

This article has presented a general survey of corrosive agents and processes that exist within what are usually considered the protective environments of museums and collections. While interventive treatments remain a viable option, both passive and active control of the environment to minimize or eliminate corrosive agents are preferred in modern conservation practice.

Environmental control may be as simple as providing a microclimate (usually below 40% RH) or the inclusion of pollution scavengers within display cases or storage cabinets, such as activated charcoal filters, zinc oxide in pellet form, or fabrics/plastics that contain small particles of silver or copper that act as sacrificial

reactive sites. Certainly, one method of controlling pollutants in a museum or storage environment is to limit the infiltration of unfiltered outside air. However, if the number of air exchanges is reduced dramatically, a buildup of pollutants can result within the closed environment. While basic filtration of museum or collection spaces is now a common standard, filtration to the level necessary for eliminating all traces of pollution is out of budgetary reach for most small institutions. Small particulates ($<1 \mu\text{m}$, or 0.04 mils) are difficult to filter, and the removal of nitrous oxides requires specialized equipment. Nonetheless, the inclusion of high-efficiency filters and activated charcoal filters within a heating, ventilation, and air conditioning system can go a long way in protecting collections. Relatively speaking, these can be installed and maintained at a modest cost, given the protection achieved. Simple and more direct methods should, of course, never be overlooked. Eliminating inappropriate materials is a well-documented success (Ref 40). Avoiding the use of alkyd paints, silicone sealants containing acetic acid, polyvinyl chloride or polyvinyl acetate adhesives, urea-formaldehyde adhesives, most wood products, vulcanized rubber products, or any other material that may emit acid, alkaline, or aldehyde by-products is an effective first step. Relatively simple methods of evaluating materials used in construction or finishing of display and storage fixtures and facilities are available and easily applied (Ref 41).

The most well known and widely used of these methods is the Oddy test (Ref 42), involving a sample of the potentially corrosive material in close proximity to or in contact with a copper, a silver, and a lead coupon that is placed in a test tube. The test is undertaken with high RH and elevated temperatures. Although the determination of whether or not the coupons have altered during the 30 day cycle remains somewhat

(a)

(b)

Fig. 8 The interaction of components of an artifact. (a) Gourd box, late 19th or early 20th century, Kasai District, Zaire. (b) Detail shows the corrosion of the copper alloy tacks due to the oil applied to the surface of the gourd during manufacture or use. Original magnification 5 \times . Conservation Laboratory, University of Pennsylvania Museum of Archaeology and Anthropology

subjective, the test is nonetheless pragmatic, direct, and easy to evaluate. The list and availability of acceptable substitutes for inappropriate materials is continually expanding. Sealing the potentially corrosive material is another option. Plywood used in the construction of exhibition cases is often sealed using aluminum/plastic laminates, such as Marvel Seal (Ludlow Corp.).

Stewardship of collections is recognized as a professional responsibility that includes evaluation and maintenance of the environment where the objects are held. The aim of these efforts is to assure the safest and most benign surroundings possible, thus assuring the future preservation of the collection. An excellent review of air sampling and monitoring approaches can be found in the book *Atmospheric Corrosion* (Ref 4), and an equally excellent review of scavengers and adsorbents is found in Hatchfield's book *Pollutants in the Museum Environment* (Ref 40).

In all the examples noted in this article, appropriate steps were taken by the conservators of the institutions to eliminate the corrosive sources acting on the objects and to avoid future introduction of other potentially damaging materials. These measures, more than any other approach, have been the most effective in preventing future corrosion within museum and collection environments. Each of the examples, the challenges they presented, and the solutions found to resolve the ongoing corrosion threats were generously provided by forward-looking institutions and conservators. Such openness and generosity assures the advance of preservation efforts.

ACKNOWLEDGMENTS

The author would like to thank Terry Drayman-Weisser, Head of Conservation for the Walters Art Museum in Baltimore; Laura D'Alessandro, Objects Conservator for the Oriental Institute Museum in Chicago; Lynda Zycherman, Conservator at the Museum of Modern Art in New York; James Coddington, Conservator at the Museum of Modern Art in New York; Donna Strahan, Head of Conservation for the Asian Art Museum in San Francisco; and Virginia Greene, Senior Conservator at the University of Pennsylvania Museum of Archaeology and Anthropology in Philadelphia, all of whom generously provided case studies; Cecily Grzywacz, Scientist at the Getty Conservation Institute, for her valuable input; and John Twilley, Conservation Scientist, for his generous advice and many insights.

Corrosion of Metal Artifacts Displayed in Outdoor Environments

L.S. Selwyn, Canadian Conservation Institute, and P.R. Roberge, Royal Military College of Canada

METAL ARTIFACTS are installed in public places to commemorate people, events, and ideas; as public art; or because they are of historical importance. The artifacts can be divided into three broad categories: unique pieces, historical metalwork, and reused pieces. The unique pieces are often custom-built and site-specific; they include works of art, sculptures, statues, monuments, commemorative pieces, war memorials, and fountains. Historical metalwork can be part of a heritage structure or a setting with historical significance; this category includes fences, gates, flagpoles, grave markers, plaques, and decorative elements on historic buildings. The reused pieces can be working artifacts that have been taken out of service and reused as commemorative pieces, such as tanks, cannons, anchors, artillery pieces, trains, aircraft, military vehicles, ships, and rockets. Many of these objects are made in part or totally of metals; copper alloys (bronze, brass) or ferrous metals (wrought iron, cast iron, steels, stainless steels, galvanized steel) are common. Aluminum, Cor-Ten (United States Steel Corp.) weathering steel, lead, zinc, and gold (gilding) are also used.

Being outdoors, cultural artifacts are exposed to uncontrolled conditions of sun, moisture, pollutants, temperature, and winds, as well as microclimates created by the location and influenced by the shape and surface detail of the artifact. They are exposed to a wide range of chemical and physical environments (acid rain, acid particulates, bird droppings), and they are also susceptible to damage by vandalism (graffiti, spray paint, theft). Windblown particles abrade sculptural details. Ultraviolet light and temperature extremes accelerate the breakdown of paints and other coating materials.

Cultural artifacts displayed outdoors in public places are intended to be highly visible. They need to be cared for and maintained; otherwise, the metal artifacts corrode and lose their heritage value and visual appeal. The composition and types of objects, their corrosion problems, and the approaches used to preserve, conserve, and maintain them are described in this article.

Environmental Factors Causing Damage

Some of the general factors are water, temperature fluctuations, freeze-thaw cycles, relative humidity (RH) fluctuations, wind load, particulate matter (sea salts, deicing salts, dirt), pollutants (sulfur dioxide, nitrogen oxides, ozone), local conditions of acidity or alkalinity, vegetation, animals, and people. Also important are design factors that generate local corrosion problems within a monument, such as dissimilar metals in direct contact, pooling water (from lack of drainage), condensed water under overhangs, and trapped water that freezes.

Environments. The location of outdoor metal monuments is classified in one of four general environments: rural, urban, industrial, or marine (Ref 1). Rural locations are relatively clean; urban locations have high levels of car exhaust; industrial locations have high pollutants levels; and marine locations have high levels of salts. Studies of the corrosion rate of small metal testpieces (coupons) in these general environments provide useful information about average corrosion rates due to macroscopic effects such as general climate and pollution conditions (Ref 2). Average corrosion rates are determined by mass-loss measurements, where metal coupons are weighed before and after a period of outdoor exposure; corrosion products are removed before weighing (Ref 3). Typical average corrosion rates for aluminum, copper, iron, lead, and zinc coupons in the four general environments are given in Table 1 (Ref 4–6).

When unprotected bare metal in a metal artifact is exposed outdoors, it interacts with water and environmental chemicals, corrodes, and forms what is referred to as a natural patina. The formation of this patina is influenced by the local microclimate. The overall condition and appearance depends on many factors, including the distance from the ground (including whether it is in contact with the ground), distance from local pollution sources, surface orientation, and degree of shielding from wind, rain, and sunlight. On outdoor bronze statues, for example, the side exposed to strong winds from the sea tends to become covered with lighter-green corrosion products than the sheltered side, which tends to be darker green (Ref 7). Horizontal or inclined surfaces on outdoor bronzes form a patina more rapidly than vertical surfaces do. Laboratory studies of copper exposed to pollutants have demonstrated an enhanced corrosion rate caused by a synergistic effect between sulfur dioxide (SO₂) and nitrogen dioxide (NO₂), and between SO₂ and ozone (Ref 8, 9). These results support the suggestion that outdoor bronzes suffer more corrosion damage when located in areas exposed to heavy traffic (where higher levels of NO_x are expected from car exhaust and possibly the winter use of deicing salt) than when located in more sheltered areas such as in the center of large parks (Ref 10).

Water. In outdoor environments, metals corrode by electrochemical processes that require water as an electrolyte. The corrosion rate of metals is negligible when the RH is low but can be significant when moisture is present to wet the surface. Electrochemical reactions are

Table 1 Corrosion rates for common metals in different kinds of outdoor environments

Metal	Rural		Urban		Industrial		Marine	
	µm/yr	mils/yr	µm/yr	mils/yr	µm/yr	mils/yr	µm/yr	mils/yr
Aluminum	0–0.1	0–0.004	~1	~0.04	0.4–0.6	0.016–0.024
Copper	~0.5	~0.02	1–2	0.04–0.08	2.5	0.1	~1	~0.04
Iron	4–65	0.16–2.6	23–71	0.92–2.84	26–175	1.04–7	26–104	1.04–4.16
Lead	0.1–1.4	0.004–0.056	1–2	0.04–0.08	0.4–2	0.016–0.08	0.5–2	0.02–0.08
Zinc	0.2–3	0.008–0.12	2–16	0.08–0.64	2–16	0.08–0.64	0.5–8	0.02–0.32

supported when there is enough adsorbed water to approach the behavior of bulk water, which happens on most clean metal surfaces above 65% RH (Ref 11), and when rain, dew, fog, or mist are present. In outdoor corrosion studies, it is often assumed that a metal surface will be wet enough to support corrosion whenever the RH is >80% and the temperature is above 0 °C (32 °F), although historic metals in Antarctica have been found to corrode above 50% RH and above -10 °C (14 °F) (Ref 12). Other factors that contribute to water condensation and metal corrosion are the presence of hygroscopic particles and surface roughness (microscopic cracks, porous particulate matter, corrosion products) that promote capillary condensation (Ref 1).

The metal corrosion rate also depends on the ionic conductivity of water, which is altered by absorption of atmospheric gases, dissolution of surface material (corrosion products), and deposition of airborne dust and salts. Exposure to wind and sun can affect condensation and the rate of drying as well as the amount of contaminants and corrosion products retained on the surface. Rain can help to keep exposed surfaces on outdoor metals less corroded than sheltered areas, where corrosive particles tend to accumulate and drying times are longer. As water flows over a metal surface, it dissolves soluble species and helps to rinse away deposited material. The rate at which metal is flushed from a surface by flowing water is known as the runoff rate and is based on the total metal concentration in collected runoff water (Ref 3, 13). The metal concentration in runoff water reflects the loss of corrosion products and can cause staining of adjacent surfaces. Studies have shown that higher runoff concentrations of copper and zinc are present in the water collected first (first flush) as the easily soluble corrosion products are removed, followed by a lower and reasonably constant concentration in subsequent volumes collected (steady state) as materials with low solubility are slowly dissolved (Ref 14). These studies also determined that the metal concentration in runoff water increased with increasing rain acidity (lower pH) and decreasing rain intensity (drizzle has the longest surface contact period). Other studies have shown that the runoff rates from copper and zinc are higher from surfaces with a low degree of inclination to the horizon (where more pollutants are deposited) and from surfaces oriented in the prevailing wind direction (Ref 15). Comparison studies of the corrosion and runoff rates for copper and zinc have shown that, on an annual basis, runoff rates are lower than corrosion rates, demonstrating that during the corrosion process, corrosion products with relatively low solubility build up on the metal surface (Ref 3).

Pollutants. The key pollutants that interact with outdoor metals and influence their corrosion rate are sulfur dioxide (SO₂), nitrogen oxides (NO_x), ozone (O₃), and chloride ions (Cl⁻). Sulfur dioxide and nitrogen oxides form acids that attack the metal directly, whereas ozone and chloride ions enhance corrosion rates (Ref 16,

17). Sulfur dioxide gas is produced by burning fossil fuels (particularly coal), by pulp and paper mills, by smelting of ores, and by natural sources such as volcanoes. Atmospheric interactions convert sulfur dioxide to sulfuric acid (H₂SO₄), which is found in acid precipitation and in atmospheric particulates. The gas-phase nitrogen oxides are by-products of the combustion of fossil fuels, and they show up in acidic rain as nitric acid (HNO₃) and in aerosol particles (Ref 16). Ozone is generated in photochemical smog by the interaction of solar radiation with nitrogen oxide gases and hydrocarbons from vehicle exhaust. Ozone enhances metal corrosion rates because it is a powerful oxidizing agent and, when combined with sulfur dioxide, can have a synergistic effect that increases the corrosion rate of certain metals (Ref 9, 17). Chloride ions are present in precipitation, with the highest concentrations identified in precipitation in coastal regions (Ref 18). The chloride ions are from sea salt particles, winter deicing salts, or atmospheric hydrogen chloride gas (HCl) produced from the combustion of coal and the incineration of waste, especially polyvinyl chloride plastics (Ref 16, 17). Chloride ions increase the corrosion rate of metals because they interfere with the formation of protective surface films and form soluble salts and complex ions with many metal ions.

Outdoor monuments are exposed to pollutants through wet and dry deposition. Metals in unsheltered exposures are affected by both wet and dry deposition, whereas sheltered metals are affected predominantly by dry deposition. Wet deposition transfers atmospheric moisture containing water-soluble species (sulfuric acid, nitric acid) to the surface of outdoor monuments (Ref 16). Dry deposition transfers dry material (gases, microscopic particles, large debris) to outdoor surfaces. Soot, for example, is a microscopic particle produced by incomplete combustion of fossil fuels and often contaminated with sulfate and nitrate ions, absorbed gases, salts, and other material. Particulate material is easily trapped by rough, textured finishes (such as sheet aluminum) or ornate three-dimensional designs (such as pressed zinc) used to decorate historic buildings or in metal sculptures (Ref 19, 20).

Dry deposited and trapped material can damage the underlying metal whenever it gets wet and traps moisture next to the metal surface for long periods of time, promoting local crevice corrosion underneath it, especially if the salts or acids present are hygroscopic. Metal sulfates deliquesce at higher RH values, and these hygroscopic salts retain moisture on the metal surface, increasing the corrosion rate. Zinc sulfate deliquesces at 89% RH; iron(II) sulfate deliquesces at 95% RH; and copper sulfate deliquesces at 97% (Ref 21). Metal chlorides deliquesce at lower RH values: iron(III) chloride and zinc chloride below approximately 10% RH, calcium chloride at 33% RH, iron(II) chloride at 56% RH, and copper(II) chloride at 68% RH (Ref 21, 22). Wet deposited material (along

with soluble ionic species from dry deposited material) participates in surface chemical reactions that produce the patina on outdoor monuments.

Sulfate ions participate in the corrosion of outdoor metals by increasing the conductivity of surface water and by interacting with many metals to form both soluble and insoluble corrosion products. The soluble compounds form first; some of these may convert into insoluble ones if they are not washed away by rain. Sulfate-containing corrosion products make up the natural patina on several common outdoor metals. On most outdoor lead, anglesite, a lead sulfate, is one of the main patina components (Ref 23, 24). On outdoor copper roofs and bronze statues, brochantite, a copper hydroxide sulfate, is the main corrosion product in the green patina (Ref 7, 25–29). A series of laboratory experiments have been carried out to study the effect of various pollutants on copper and on copper corrosion products exposed to various pollutants in order to obtain a better understanding of the natural patination process on outdoor copper and bronze monuments (Ref 8–10, 30–33). These studies have demonstrated the importance of the sulfate ion in the development of brochantite in the green patina on outdoor bronzes and its relative stability (Ref 30, 33).

Nitric acid and nitrate ions dissolve in surface water and increase its conductivity. The nitrate ion rarely becomes incorporated into patina layers, presumably because of the high solubility of metal nitrate compounds (Ref 24, 34–36).

Chloride ions can cause serious corrosion problems on many outdoor metals. Not only do chloride ions contribute to the conductivity of surface water, they also promote localized pitting corrosion because they interfere with the formation of protective surface films. Chloride ions form soluble salts and complex ions with many metal ions, thus promoting diffusion away from the metal surface rather than precipitation directly on the surface. Once a pit has initiated at a local surface defect, the dissolution of the metal within the pit causes the local chemical environment to become substantially more acidic than the surrounding bulk environment (Ref 37). Chloride ions from the surrounding electrolyte diffuse into the pit to maintain charge balance with the metal cations. When iron, for example, corrodes in the presence of an acidic solution containing chloride ions, a cyclic corrosion process (a corrosion cycle) is initiated, and this can cause pitting and perforation of the metal (see also the discussion on corrosion of iron alloys in the section “Corrosion of Common Metals used Outdoors” in this article).

Iron and steel objects suffer the worst damage by chloride ions. Rusting, perforation, and component loss have been observed in historic iron fences running alongside busy roads where winter snow, contaminated with deicing salts, is pushed on top of the fence. Paint failure is often the result of inadequate surface preparation that has left hygroscopic salts on the metal surface.

Aluminum artifacts suffer from pitting caused by chloride ions (Ref 36, 38, 39). Aluminum sculptures exposed to chloride ions become covered with spots (white or darkened by dirt), which are gelatinous deposits of aluminum hydroxide covering deep pits (Ref 40). Chloride ions are a contributing factor to the often severe pitting observed on outdoor bronzes, especially when they are located close to roads where deicing salts are used and the surface is frequently splashed with salty water (Ref 41, 42). On outdoor bronzes, the exposure to chloride ions may result in the formation of green copper(II) chloride hydroxides and occasionally the copper(I) chloride; these corrosion products suggest corrosion processes related to bronze disease, a corrosion problem normally associated with archaeological bronzes. For more information on bronze disease, see the article "Corrosion of Metal Artifacts in Buried Environments" in this Volume.

Acid Conditions. The pH of the moisture lying on the metal surface is a crucial factor in the dissolution of any protective surface layer. The pH of clean rain water is controlled by the dissolution of atmospheric carbon dioxide and typically has an equilibrium pH of approximately 5.6 (Ref 24). The presence of carbonate and bicarbonate ions in atmospheric moisture is important for the formation of light-colored patinas on lead and zinc. Hydrocerussite, a lead carbonate hydroxide, forms on outdoor lead, and hydrozincite, a zinc carbonate hydroxide, forms on outdoor zinc.

Acid precipitation (with a pH less than 5.6) develops from the dissolution of water-soluble acids (sulfuric acid, nitric acid, hydrochloric acid). Organic acids (formic, acetic, oxalic) also contribute (Ref 43). Historical assessments of sulfur dioxide concentrations in the United States and Europe show a marked increase between 1890 and the mid-1900s, followed by a leveling off as a result of strict emission controls (Ref 16, 44). In developing countries, sulfur dioxide concentrations may continue to increase because of the continued use of high-sulfur coal (Ref 16). The concentrations of nitrogen oxides and ozone have also increased during industrialization but have not declined during recent decades because of continued burning of fossil fuel in motor vehicles (Ref 33, 45). Since the beginning of the Industrial Revolution in the mid-18th century, the pH of precipitation has decreased (become more acidic) in many places around the world (Ref 16). In Europe, the pH of precipitation is thought to have decreased from approximately 5.4 in 1890 to 4.3 (more acidic) by 1980, while in urban areas of the Northeastern United States, the precipitation pH was estimated at 3.4 for the period 1920 to 1950 but had increased to 4.3 (less acidic) by 1980 (Ref 17). High acidities (pH < 4) can occur on the surface of outdoor metals exposed to acidic fogs or by evaporation of surface electrolytic solutions (Ref 30, 46). Local acidity can damage the surface of metals outdoors by dissolving corrosion products and by attacking the metal. In general, metals

experience a thinning or dissolution of protective corrosion-product layers, followed by attack of the bare metal, with exposure to acidic solutions. The solubility of the iron corrosion products that typically form on outdoor iron increases as the pH drops below 6 (Ref 30, 47). For patinated copper, laboratory studies have observed an increase in the copper concentration in runoff water with a decrease in pH (from 4.3 to 3.5); this demonstrates an increased solubility of low-solubility copper compounds with increasing acidity (Ref 14). Other laboratory studies have demonstrated that the patina on copper can be fully dissolved and bare metal exposed if the pH drops below approximately 2.5 (Ref 30, 47). Unsightly grooves develop on lead and zinc roofs as acidic solutions (from acid rain or from organic acids leached from wooden shingles, lichen, or moss) flow over their surfaces. Lead corrodes faster in solutions with pH < 5, and zinc corrodes more rapidly when the pH is < 6 (Ref 24, 48–50). Aluminum corrodes quickly in solutions with pH < 4 (Ref 38, 51, 52).

Alkaline Conditions. Copper alloys and iron alloys are generally not affected by alkaline conditions, but aluminum, lead, and zinc are. These latter three metals corrode faster in alkaline solutions because the corrosion products are more soluble at high pH, and any protective corrosion layer becomes thinner or dissolves (Ref 53). Lead corrosion products are soluble in alkaline solutions with pH > 10 (Ref 24, 48, 49). Zinc oxide and zinc hydroxide are only stable in the pH range of 8 to 12 (Ref 50). The hydrated aluminum oxides responsible for the protection of aluminum become soluble in alkaline solutions with pH > 9 (Ref 38).

Alkaline solutions are present during the curing process in cement, lime-based mortars, and concrete. If these materials remain wet and if the pH is high, contact between them and aluminum, lead, or zinc may cause these metals to corrode or be etched. Lead surfaces, for example, become stained with colored lead monoxides (red litharge, yellow massicot, or alternating layers of red and yellow) when exposed to alkaline environments (Ref 23, 54, 55). It can be dangerous to use alkaline paint strippers on outdoor painted aluminum, lead, or zinc artifacts, because of the possibility that the alkaline stripper will damage the underlying metal.

Temperature. Large sculptures and monuments, particularly those made of zinc, lead, and aluminum, may suffer mechanical failure, with tearing, buckling, and cracking caused by differential thermal expansion and contraction from daily and seasonal temperature fluctuations (Ref 52). Zinc, lead, and aluminum have higher coefficients of linear expansion compared to materials such as brick, concrete, glass, and stone, although there are certain materials (elastomers, polyethylene, ice, epoxy) with much higher values (Table 2). In addition to expansion and contraction problems, zinc and lead also have a tendency to creep (flow slowly due to gravity) under their own weight, and so, large pieces may start to distort, lean, sag, or

bulge (Ref 52, 56, 57). In the past, concrete has been used to fill lead and zinc sculpture as a means to provide support against the tendency of these metals to undergo creep. Concrete has also been used to fill the interior of hollow cast iron sculptures (Ref 58). Unfortunately, concrete shrinks on setting, typically leaving narrow gaps between the fill and the metal. Water eventually seeps into the gap, keeps the metal damp, and causes the metal to corrode. When metal, particularly iron, corrodes within a confined space, the increase in volume caused by the formation of corrosion products can place pressure on the surrounding metal and may cause it to crack. Similarly, if water freezes within a confined space, it expands and can also cause the metal to crack (Ref 57, 58).

Vegetation. Historic pieces located close to the ground often suffer corrosion caused by moisture trapped by adjacent shrubs and plants, or when flowers and wreaths are left uncollected and hold moisture next to the metal surface (Ref 59). Fast-growing ivy can encase historic wrought iron fences, disrupt paint, and trap moisture, which promotes rusting. Soil can blow in and fill in the gap between a fence and the ground. A metal sculpture in the shade of trees can remain damp for long periods of time. Trees and shrubs can also cause damage because of aggressive root systems, dropping branches, leaves or seeds, or exuding sticky material. Organic acids (e.g., acetic acid) can be leached from wooden shingles, and oxalic acid can be leached by water running through moss and lichen (Ref 60).

Animals. The complex structures of outdoor metal artifacts often provide convenient nesting grounds or perches for insects, birds, and animals. Nests from wasps, birds, and squirrels have been observed on outdoor sculptures (Ref 28, 61). Birds are often seen sitting on outdoor statues (Fig. 1), where they can scratch the finish and deposit material that causes the metal to

Table 2 Linear expansion coefficient of some common materials

Wood, red oak, perpendicular to grain	31–39

corrode. Nesting material traps moisture next to the metal surface, and degrading organic material introduces additional salts and acidic by-products (such as acetic acid) to the water layer.

Fig. 2 Detail of damage by galvanic corrosion of an iron staff in contact with a cast bronze hand on a statue of *Mercury* (date 1962) located in Kingston, Ontario. Courtesy of Pierre Roberge, Royal Military College of Canada. Photograph 2003

Ants and other insects produce formic acid (Ref 51, 52). Bird urine contains varying amounts of ammonia (NH_3), uric acid ($\text{C}_5\text{H}_4\text{N}_4\text{O}_3$), and phosphates (PO_4^{3-}), and the pH varies from 5 to 8 (Ref 62, 63). Uric acid, ammonia-containing compounds (e.g., ammonium copper sulfate dihydrate, $\text{Cu}(\text{NH}_4)_2(\text{SO}_4)_2 \cdot 2\text{H}_2\text{O}$), and phosphates (e.g., libethenite, pyromorphite) have been identified on outdoor bronze statues (Ref 28). Researchers identified pyromorphite, a lead chloride phosphate ($\text{Pb}_5\text{Cl}(\text{PO}_4)_3$), on the gilded bronze *Golden Boy* located on top of the Legislative Building dome in Winnipeg (Ref 64). Bird excrement supports the growth of fungal spores that can lower the pH significantly (e.g., from 7 to less than 4) and damage the underlying metal (Ref 65).

People. Outdoor artifacts are subject to vandalism, especially those situated in isolated locations in parks, gardens, or cemeteries, or if their design and location make them accessible (Ref 42, 59, 66). Graffiti (applied using spray paint, felt-tip markers, paint-filled balloons, or sharp objects) can be a problem; rapid removal of graffiti helps discourage future vandalism. Monuments and their immediate surroundings can be damaged by group activities (e.g., skateboarding, partying) and unsightly garbage (e.g., uneaten food, glass bottles, cigarette butts). Sculptures can be damaged when they are repeatedly touched or climbed on; thin areas of soft metals can be crushed, coatings scratched, bare metal exposed, and small accessories bent or stolen. The bronze sculpture of Denmark's *Little Mermaid* has been decapitated more than once, and statues of political leaders have been pulled down and removed during times of strife. Finally, outdoor artifacts are damaged by neglect; they all need a program that provides some degree of protection against vandalism

(e.g., good lighting) as well as regular maintenance.

Design can result in corrosion problems. One common design problem is the direct contact between two dissimilar metals that can lead to accelerated corrosion of the more active metal (galvanic corrosion). Design details that allow water to collect and lie stagnant for long periods of time promote corrosion.

Galvanic corrosion is the accelerated corrosion of a metal in electrical contact with a more noble metal (or a nonmetallic conductor) in an electrolyte. Many outdoor works of art and historically significant artifacts are constructed with two or more metals in direct contact. Artists use combinations of metals to achieve a certain look (e.g., brass on cast iron used in Brancusi's *Infinite Column*, as discussed in Ref 67). Initially, galvanic corrosion is not a problem, because a coating or paint layer isolates the metals from atmospheric moisture. However, over time, if the coating or paint is not maintained and these metals become exposed to water, the more active metals will suffer galvanic corrosion. A number of examples of galvanic corrosion are given subsequently.

Large metal sculptures are usually supported with an internal structure (an armature) made of another metal, often iron. Moisture enters into the interior of these sculptures (through openings or by condensation), and usually, the iron suffers from galvanic corrosion. The corrosion rate of the iron is accelerated when it is in direct contact with more noble metals, such as copper and bronze. The formation of rust exerts huge destructive forces on surrounding metal and can cause it to crack; rust staining of adjacent material is also a problem. Figure 2 shows damage to a cast bronze hand holding a rusting iron staff. Figure 3 illustrates galvanic corrosion

A look inside the *Statue of Liberty*

Fig. 3 Galvanic corrosion between copper and wrought iron on the *Statue of Liberty*, causing accelerated corrosion of the iron

on the *Statue of Liberty* (officially titled *Liberty Enlightening the World*) where the wrought iron armature was originally in direct contact with copper (Ref 25). Furthermore, severe rusting of iron bolts can dangerously weaken the attachment points (Ref 68).

Historic iron artifacts (iron cannons, wrought iron gates) suffer accelerated corrosion when brass plaques are directly attached to them. Aluminum suffers galvanic attack when it is in contact with copper or copper-base alloys, such as when brass screws are used to attach lighting elements to an aluminum sculpture (Ref 38). Zinc also suffers galvanic attack when it comes in contact with iron. This is used to advantage in zinc-coated (galvanized) steel but can also cause corrosion problems. If, for example, a pure zinc decorative element or a small piece of galvanized iron is in direct contact with iron (especially a large surface area of iron), then the zinc component suffers accelerated corrosion (Ref 52, 69).

Zinc sculptures that were electroplated with copper (a process that allowed zinc sculptures to be patinated to resemble more expensive bronze sculptures) and then left outdoors suffer from galvanic corrosion. The surface suffers from severe pitting at breaks in the copper where local galvanic cells are created (Fig. 4). The more-active zinc suffers from accelerated corrosion, pits develop and become covered with white

zinc corrosion products, and the surface of the sculpture becomes covered with unsightly pimples (Ref 56).

Local galvanic corrosion cells can develop if more-noble metal ions plate from a solution onto the surface of an active metal (Ref 20, 38, 41). This can happen, for example, when rain flows first over a corroding bronze sculpture (where it picks up copper ions in solution) and then flows over and plates onto aluminum letters set in the stone below. The copper ions are reduced to copper metal, and at the same time, the aluminum corrodes and aluminum ions go into solution. Once the copper is plated, it leads to serious attack of the aluminum due to the galvanic cell that is established, and eventually, pitting will occur in the aluminum as it corrodes (Ref 38). Local corrosion cells can also form if steel wool or steel brushes are used to clean artifacts made from other metals. Tiny iron pieces can become trapped in the artifact surface, where they rust and cause staining.

Detailing. The design of a work of art or a heritage object often creates areas where water collects. The expansion force of the corrosion products formed in a confined space (oxide jacking) can cause considerable distortion. Sculptures made of weathering steel can suffer from severe corrosion where water pools because of inadequate drainage (Ref 70, 71). Hollow cast bronzes can crack where trapped water expands during freezing; bronze sculptures usually contain drainage holes (called weep holes) to prevent water from becoming trapped in restricted areas (Ref 42). Heritage vehicles and other complex multiple-part artifacts, especially those containing iron, can suffer severe crevice corrosion where water becomes trapped underneath bolts and gaskets, between unsealed joints (bolted or overlapped seams), or in cracks in poor welds (Ref 72).

Serious corrosion problems, including perforation, can occur where a thin layer of water condenses (often due to poor ventilation) on metals, particularly on the underside of zinc and lead used in historic roofing (Ref 20, 23, 73, 74). This form of corrosion, called underside or condensation corrosion, occurs where water repeatedly condenses as a thin film. Thin water films are nearly saturated with dissolved oxygen, and so, the corrosion rate of a metal is more rapid when covered by a thin film of water compared to a thicker layer. Pollutants or other dissolved materials can increase the acidity of the water and interfere with the development of an adherent corrosion film that usually develops on these metals under conditions of good ventilation. Corrosion products tend to precipitate away from the metal surface, usually as loose white material (called active corrosion on lead and white rust on zinc). More severe corrosion is often encountered where lead and zinc sheets are adjacent to or supported by wood (with oak and cedar being the worst), which releases volatile organic acids such as acetic or formic acids (Ref 51). These acids form soluble compounds with lead and zinc.

Corrosion of Common Metals Used Outdoors

The corrosion processes experienced by copper, iron, lead, zinc, and aluminum—metals commonly used for artifacts in outdoor environments—are discussed in this section. When left uncoated, these metals undergo uniform corrosion and develop a corrosion-product layer. The chemical name, mineral name, and chemical formula for some of the common corrosion products found on metals exposed outdoors are listed in Table 3 (copper), Table 4 (iron), Table 5 (zinc), Table 6 (lead), and Table 7 (aluminum).

Copper Alloys. Relatively pure copper sheets were used to make the outer shell of the 46 m (151 ft) tall *Statue of Liberty* in New York City (Ref 25). Copper sheet is still a popular roofing material, especially on historic buildings (Ref 25, 52, 75). Bronze has been used since antiquity as a casting material for statuary (Ref 76). The large (13 m, or 43 ft, high) bronze of *Great Buddha of Kamakura* in Japan was cast in the 13th century (Ref 77). Another large (11 m, or 36 ft, high) bronze cast in the late 19th century is that of *William Penn*, which sits on top of the Philadelphia City Hall (Ref 52, 68). Although many outdoor bronze statues are unique, there are examples where many copies of the same statue exist. There are some 50 copies of a statue known as the *Hiker* located throughout the United States (Ref 78). Cast bronze statues are hollow, and the larger ones are made of several pieces joined together that may be supported with an internal armature that, in the past, was usually wrought iron. Traditionally, newly cast bronzes are treated with a corrosive chemical solution to produce an intentional patina, called an artificial patina, so the color could be determined by the artist or by the foundry (Ref 79, 80).

Copper alloys generally have good resistance to corrosion in outdoor environments (Table 1). When uncoated copper alloys are exposed outdoors, they undergo relatively uniform corrosion; any intentional patina gradually changes as the surface corrodes. The copper interacts with the environmental species and forms new corrosion products, referred to as a natural patina. Some corrosion products identified on corroded outdoor copper alloys are listed in Table 3 (Ref 7, 26, 28). Most copper(II) compounds are green or blue (Ref 81). The formation of an adherent layer of (usually green) corrosion products on copper helps to slow its corrosion (Ref 80). This naturally formed green patina is often not the artist's original intent, but, because the change from the original artificial patina was slow, the general public tends to forget the original patina color, and many people believe that all bronze sculptures are supposed to be green.

It can take from approximately 8 to 20 years for outdoor copper roofs to develop their characteristic green patina (Ref 82). The rate at which

Fig. 4 Pinhole corrosion on a copper-plated cast zinc statue of *Liberty Enlightening the World* after outdoor exposure. The statue (127 cm, or 50 in., tall) was modeled after Auguste Bartholdi's original model for the *Statue of Liberty*, and many copies were sold to raise money. It was cast in zinc, plated with copper, and given an imitation bronze patina by the foundry Avoiron in Paris sometime between 1878 and 1886. the green patina forms depends on several factors, including RH, pollution levels, and local acidity. Initially, as the copper corrodes outdoors, it develops a dark layer of cuprite, a

copper(I) oxide. Over time, this dark patina gradually changes to a green one as insoluble copper(II) compounds form over the cuprite layer (Ref 83). After decades of exposure, bronze

statues can develop a patchy and streaked appearance with alternating black and light-green areas (Ref 28, 84).

The presence of tin in bronze alloys plays a role in determining how the metal corrodes. Tin forms insoluble tin oxides, such as romarchite (SnO) and cassiterite (SnO₂) (Ref 28), which tend to be cathodic relative to the copper alloy, and the subsequent corrosion behavior is the selective dissolution of copper (Ref 27). In exposed areas, a thick layer of corrosion products does not build up, because of periodic washing by rain. These exposed areas tend to be an overall light green, and the main corrosion product is brochantite (Ref 7, 25–29). This surface can develop pits (Fig. 5) as well as small islands of black crusts standing above lower green areas, a process probably related to microsegregation in the alloy (Ref 27, 84, 85). A potential difference of 280 mV has been measured between the anodic green areas and the cathodic black ones (Ref 86). Areas sheltered from rain tend to be black, in part because of the accumulation of debris, soot, pollutants, and other material. These darker areas often contain a complex mixture of dark particulate matter (e.g., quartz, soot), cuprite, green copper(II) hydroxide sulfates (e.g., brochantite, antlerite), and, if chloride ions are present in the environment, green copper(II) chloride hydroxides (e.g., atacamite, clinoatacamite, paratacamite) (Ref 7, 27–29).

Sulfate Formation. Copper(II) hydroxide sulfates form on outdoor copper alloys when sulfate ions (e.g., from acid rain) dissolve in surface water and react with the underlying material. Brochantite is usually detected in the green rain-washed areas (Ref 7, 27–29). Antlerite is usually detected in sheltered areas that favor the accumulation of debris (Ref 7, 27–29). Antlerite precipitates under more acidic conditions than does brochantite (Ref 83, 87). Laboratory studies have shown that once brochantite and antlerite have formed, they remain unaffected by exposure to humid air containing only sulfur dioxide, mixtures of sulfur dioxide and ozone, and mixtures of sulfur dioxide and nitrogen dioxide (Ref 33). However, when copper hydroxide sulfates

are exposed to an aqueous solution of sodium chloride in laboratory studies, they do convert to copper chloride hydroxides (Ref 10). Other copper(II) sulfates (e.g., chalcantite) and copper(II) hydroxide sulfates (e.g., posnjakite) have occasionally been identified on outdoor copper alloys (Ref 7, 26, 88). These sulfates are considered transitory or intermediate compounds, indicating recent copper corrosion (Ref 26, 30). They can be washed away by rain water or converted to more stable copper(II) hydroxide sulfates, such as brochantite.

Chloride Formation. Copper(II) chloride hydroxides form on outdoor copper alloys when the surface is contaminated by high levels of chloride ions (present in marine environments, nearby use of deicing salts, and air pollution). Insoluble copper(II) chloride hydroxides (e.g., atacamite, clinoatacamite, paratacamite) have been identified on copper alloys exposed outdoors (Ref 7, 27–29). On occasion, copper(I) chloride (nantokite) has also been identified (Ref 27–29). Recent work shows that the x-ray diffraction reference pattern PDF 25-1427 had been incorrectly assigned to paratacamite (rhombohedral) and instead corresponds to a monoclinic crystal structure, newly named clinoatacamite (Ref 89). Therefore, past identification of paratacamite on copper alloys may be clinoatacamite. Laboratory studies have demonstrated that when atacamite is exposed to humid SO₂-containing air, it converts to soluble compounds (e.g., copper(II) sulfate, copper(II) chloride) that are not protective and can stimulate further corrosion of the underlying metal (Ref 10, 31–33). The presence of atacamite or other green copper(II) chloride hydroxides and occasionally the copper(I) chloride nantokite suggests bronze disease, a corrosion process normally associated with archaeological bronzes. More information on bronze disease is in the article “Corrosion of Metal Artifacts in Buried Environments” in this Volume.

Carbonates. Although copper(II) carbonate hydroxides can form on copper corroding in solutions containing carbonate ions, they have only rarely been identified on outdoor copper alloys. Malachite, for example, has been identi-

fied on outdoor bronze statues adjacent to damp limestone (calcium carbonate) (Ref 29). It is likely that any copper(II) carbonate hydroxides that do form are gradually converted to copper(II) hydroxide sulfates whenever the surface is exposed to water containing sulfate ions (Ref 90).

Other notable compounds identified on outdoor bronzes include copper sulfides (e.g., chalcocite, djurleite, geerite), copper oxalates, and gypsum (Ref 28, 29). The copper sulfides may be from the reaction of the copper alloy with hydrogen sulfide, especially if the copper alloys are close to pulp and paper mills. Copper oxalates could form because of exposure to oxalic acid, which is secreted by microorganisms such as fungi and lichens and which is a component of acid fog, rain, and mist in urban areas (Ref 43, 60). White accretions of gypsum (CaSO₄ · 2H₂O) sometimes develop on the outside of sculptures when residual casting material (e.g., plaster of Paris, CaSO₄ · ½H₂O) on the inside is dissolved and redeposited on the outside as water seeps through cracks and pores in the casting (Ref 28, 42).

Staining. The corrosion of copper alloys often causes green staining of adjacent material, especially porous stone or concrete (Ref 7, 20). When copper ions are washed off corroding copper, they can become trapped in adjacent material, where they react with other environmental ions and form a green stain of copper(II) compounds (e.g., brochantite, atacamite).

Iron Alloys. Various iron alloys have been used for outdoor works of art or in the construction of heritage buildings and heritage artifacts (Ref 52). In the past, traditional wrought iron (handmade iron with a characteristic fibrous structure due to inclusions of slag) was used for many decorative and functional items, with the peak in wrought iron production occurring in approximately 1850 (Ref 51). Examples include small items such as decorative wrought iron balconies, gates, and fences, and large structures such as the Eiffel Tower in Paris, the internal support structure for the *Statue of Liberty*, and the iron pillar of Delhi (Ref 25, 52, 75, 91). Cast iron is another traditional material, and it is used

to make fountains, cannons, building facades, benches, lamps and lamp posts, domes, and even bridges (such as the first European cast iron bridge built in 1781 in Ironbridge, England) (Ref 52, 58). Carbon steels are present in many modern heritage objects and military monuments (Ref 72, 92). Corrosion-resistant stainless steels are popular for polished metal sculptures and as roofing or cladding. In 1930, stainless steel was used to finish the dome on the Chrysler Building in New York City (Ref 93). Weathering steels (Cor-Ten) have been used since the 1960s in architecture and for outdoor sculptures, because this material, when left unpainted, develops a natural dark-brown patina (Ref 71). Weathering steel was used to make the large figure (15 m, or 49 ft) designed by Picasso for the Daley Plaza in Chicago (1967) and known locally as the *Chicago Picasso*.

Most iron alloys rust if they are exposed outdoors without a protective coating (Ref 35, 94). The rust layers that form on corroded iron alloys are porous, poorly adherent, and often cracked. They offer little protection to the underlying metal against the penetration of moisture. The cracking and spalling of rust layers is caused by the formation of new iron corrosion products that have molar volumes approximately three times greater than the molar volume of iron. In general, carbon steels have a higher corrosion rate outdoors than aluminum, copper, lead, or zinc (Table 1), especially in industrial and marine environments (Ref 95).

Some corrosion products that form on iron when it is exposed outdoors are listed in Table 4 (Ref 35, 94, 95). The corrosion of iron is an electrochemical process: the anodic reaction is the oxidation of iron to Fe(II) ions, and the cathodic reaction is usually the reduction of dissolved oxygen. Once Fe(II) ions are present in solution, a variety of corrosion products can form and precipitate. The rust layers generally include an inner layer of black magnetite (plus other amorphous iron corrosion products) and an outer layer of iron hydroxide oxides (e.g., goethite, lepidocrocite), which have the familiar orange, red, and brown colors of rust (Ref 35). Other iron corrosion products can form, depending

on the environmental ions present in surface water.

Sulfate ions accelerate the rusting of iron (Ref 35, 95). When iron rusts in the presence of sulfate ions, soluble iron(II) sulfate forms (Ref 1). Upon evaporation of water, various iron(II) sulfate salts (with different waters of hydration) can crystallize (e.g., rozenite, melanterite, siderotil), but in the presence of moist air, iron(II) sulfate undergoes oxidation and hydrolysis according to:

Iron oxide hydroxides precipitate (e.g., lepidocrocite, goethite), and the sulfate ion is released as sulfuric acid, making the sulfate ion available to again attack the remaining metal, creating an ongoing corrosion cycle. Some of the sulfate ions are removed from solution as they become incorporated into the rust layer as relatively insoluble iron(III) hydroxide sulfates, such as butlerite, or, if sodium or potassium ions are present, as jarosite or natrojarosite (Ref 35).

Chloride ions are easily transported through a rust layer where they can attack the underlying metal, form soluble iron chloride salts and complexes, promote pitting, and cause rapid, disfiguring corrosion (Ref 35). The hygroscopic nature of iron chloride salts also promotes the formation of blisters (referred to as weeping or sweating). Only rarely do chloride ions become incorporated into the rust layer, but they do promote the formation of iron hydroxide oxides. Laboratory studies have shown that if iron corrodes in solutions containing low concentrations of chloride ions, goethite and lepidocrocite precipitate (Ref 96). However, if the chloride ion concentration is high, another iron hydroxide, known as akaganéite, can precipitate. Akaganéite is normally written $\beta\text{-FeO}(\text{OH})$, but because chlorine atoms stabilize its structure (they are located inside tunnels), a chemical formula more representative of its chlorine content is $\text{FeO}_{0.833}(\text{OH})_{1.167}\text{Cl}_{0.167}$ (Ref 97–99). For more information on akaganéite formation and weeping on iron, see the article “Corrosion of Metal Artifacts in Buried Environments” in this Volume. Chloride ions accelerate the corrosion rate of iron because they participate in the following corrosion cycle (Ref 100):

The crucial factor in this cycle is that the chloride ions form a soluble salt with iron(II) ions, and it is this solubility that allows the cycle to proceed. If the iron chloride salt were insoluble, it would precipitate and the cycle would be broken.

Crevice corrosion can occur on any outdoor metal artifact, but it most often damages iron artifacts, especially large heritage pieces that are not being maintained. Crevices exist at metal-to-metal joints or underneath material held against a metal surface, such as gasketing, biofouling, or external deposits (Ref 37). Because the diffusion of oxygen into a crevice is restricted, an oxygen concentration cell develops, and the region inside the crevice corrodes because it is anodic relative to the region outside the crevice. Both the acidity and the concentration of dissolved metal ions increase inside the crevice, causing a significant increase in the iron corrosion rate within the crevice. Visual evidence of crevice corrosion is often rust leaching out from a seam.

Weathering steels are low-carbon steels with minor additions of other alloying elements (copper, phosphorus, manganese). When exposed outdoors, weathering steels develop a dense adherent oxide film that helps slow the corrosion rate relative to plain carbon steels (Ref 35). The minor alloying elements have a beneficial effect in forming an inner rust layer (consisting mainly of goethite) that is a good barrier to oxygen and water (Ref 101). The formation of a stable patina of rust depends on alternating wet and dry cycles. It can take years for the patina to develop on weathering steel, and during its formation, the runoff can leave stains on adjacent material (Ref 70, 71). The patina can be uneven and streaked (Ref 102). Pooling of water is a major enemy of weathering steels because, if they remain immersed in water, they will corrode with a rate similar to that for plain carbon steel and therefore become susceptible to significant rusting, delamination, and perforation (Ref 70, 71).

Stainless steels, with their chromium-rich oxide film, and other corrosion-resistant specialty iron alloys remain relatively uncorroded in an outdoor environment (Ref 35). Pitting can occur on a microscopic level beneath crevices at inclusions or flaws in the passive layer. A sign of pitting is the formation of small rust spots on the surface of stainless steel. Because chloride ions interfere with the formation of the passive oxide film, they are usually responsible for initiating pitting on stainless steels. Outdoors, where stainless steel is exposed to wind-blown material, dirt can build up and trap moisture and contaminants next to the metal surface. If the oxide film on stainless steels is damaged by chloride ions, oxygen or some other oxidizing agent is needed to reform the film. If dirt restricts oxygen, then the oxide film may not reform, and the stainless steel can then rust. Two popular stainless steels for architectural use outdoors are types 304 (UNS S30400) and 316 (UNS S31600) (Ref 20). In environments contaminated by chloride ions or industrial pollutants, type 316 stainless steel, which contains 2 to 3% Mo, is preferred because it is more corrosion resistant than type 304.

Zinc had its greatest popularity for statuary between 1850 and 1920, when it was used for

mass producing low-cost alternatives to bronze or lead. Zinc was used for sculptures, cemetery monuments, architectural elements (roofing, decorative tiles, moldings, animal heads, gargoyles), fountains, and grave markers (Ref 51, 52, 56, 61). In the United States, inexpensive zinc statues and American War memorials (many of which were ordered directly from catalogs) were used to adorn city halls, county courthouses, parks, post offices, and cemeteries (Ref 52, 56, 57). Larger pieces were made by joining together smaller cast or stamped pieces using soft solder. Some zinc sculptures were finished to imitate other (more expensive) materials by painting, electroplating with copper (and patinating to resemble bronze), or even gilding (Ref 56, 57). In the United States, the zinc pieces used in Civil War memorials and cemetery monuments were often left uncoated; they were sandblasted to a matte, stonelike finish and then placed outdoors and allowed to develop a uniform light-gray patina (Ref 52, 56, 57). The use of zinc in sculptures started to decline in approximately 1920, after its poor durability outdoors had been recognized. Zinc is used in modern metal works of art, sometimes as cladding.

In outdoor environments, the corrosion rate of zinc is much lower than iron. This is one of the reasons why zinc is used as a protective coating on iron (galvanized steel). The other reason is that zinc corrodes preferentially to steel because zinc is the more anodic of the two (Ref 50). In general, zinc is more resistant to corrosion in rural atmospheres and less resistant to corrosion in industrial environments polluted with sulfur dioxide. Zinc usually undergoes uniform corrosion when exposed outdoors, and some of the corrosion products that can form are listed in Table 5 (Ref 34, 50). When zinc is placed outdoors, it gradually changes from a bright metallic finish to a matte, gray patina as the zinc undergoes uniform corrosion and forms a somewhat protective film of adherent, relatively insoluble white zinc corrosion products (Ref 34). When zinc corrodes, zinc oxide and zinc hydroxide form first. These corrosion products react with various soluble species (carbon dioxide, chloride ions, sulfate ions) present in surface moisture and convert into other insoluble or soluble zinc corrosion products (Ref 34, 50). In unpolluted environments, zinc reacts with dissolved carbon dioxide gas, and relatively insoluble zinc compounds (e.g., hydrozincite) form in a protective layer (Ref 34, 50, 103). This carbonate layer, however, does not completely protect zinc from further corrosion, especially in marine, urban, and industrial atmospheres contaminated by acid rain, chloride ions, and sulfate ions. Under acidic conditions, the carbonate layer dissolves, and the zinc reacts with soluble contaminants. Zinc reacts with chloride and sulfate ions, at least initially, to form soluble zinc chlorides and zinc sulfates (Ref 34, 50). These soluble salts are readily washed away by rain, which can lead to white staining on adjacent dark building material (Ref 52). Zinc chlorides and zinc sulfates are

hygroscopic and, if not washed away, gradually transform into insoluble zinc chloride hydroxides, zinc hydroxide sulfates, and other zinc compounds (containing both chloride and sulfate ions) that become incorporated into the corrosion layer (Ref 104, 105).

Lead is one of the metals used since antiquity (well before 3000 B.C.) (Ref 106). The Romans employed it for water pipes. Cast lead was popular for garden ornaments in England during the late 17th and 18th centuries; many were painted to imitate stone, and some were even gilded (Ref 51). Lead can also be found in roofing, sculptures, fountains, ornate 18th century cisterns, lead comes in stained glass windows (dating as far back as the 12th century), lettering in stone, spacers between stone and as a water barrier under stone, and grout to set iron bars in masonry (Ref 52). It also shows up in soft solder (lead-tin alloys), old pewter (lead is excluded from modern pewter), and in architectural cladding such as lead-coated or terne-coated metals (terne, which means dull, is a lead-tin alloy) (Ref 20). Today, because of health and environmental factors, the use of lead is severely restricted. When used outdoors, for example, the corrosion of lead can result in the amount of lead in precipitation runoff exceeding safe limits (Ref 107).

Lead has a generally good resistance to corrosion in outdoor environments, with its corrosion rate being greater than aluminum, similar to copper (depending on the environment), and smaller than zinc and steel (Table 1). Lead undergoes uniform corrosion when exposed outdoors, and some corrosion products are listed in Table 6 (Ref 23, 107–109).

When lead is first placed outdoors, it forms a thin, almost transparent layer of lead oxides, predominantly the yellow massicot but also some red litharge (Ref 23). Note that the term *litharge* can have two meanings: it can refer specifically to the red lead monoxide (α -PbO) or collectively to lead monoxides that can exist in two polymorphs (α -PbO and β -PbO). The initial patina that develops on outdoor lead artifacts contains white compounds (usually hydrocerussite but sometimes also cerussite) formed by the reaction of the lead oxides with carbon dioxide dissolved in surface water (Ref 23, 107–109). Hydrocerussite forms an adherent, relatively insoluble layer that decreases the corrosion rate of the lead.

Over time, other insoluble lead compounds also form as the hydrocerussite reacts with other dissolved species. Lead sulfite and lead sulfate (anglesite) form on lead in environments polluted with sulfur dioxide (Ref 23). Chloride-containing lead compounds do not appear to be incorporated into the corrosion layer (Ref 24, 107). The most common minerals detected on outdoor lead are anglesite, hydrocerussite, and cerussite (Ref 24).

Aluminum. One of the earliest examples of the use of aluminum is the pyramidal aluminum cap at the top of the Washington Monument (Ref 52). The condition of the aluminum cap in 1999 is shown in Fig. 6; it was cast at great

expense in 1884. Aluminum metal was not widely used until after 1886, when it became more affordable as a result of the development of the Hall-Heroult electrolytic process. Another example is the cast aluminum figure of *Eros* on the Shaftesbury Memorial in Piccadilly Circus, London (unveiled in 1893) (Ref 110). Today, aluminum is used for architectural purposes, outdoor sculptures, and airplanes exhibited outside airports or aviation museums (Ref 20, 111).

Aluminum usually corrodes outdoors more slowly than other common metals (Table 1) (Ref 5, 36). The corrosion rate does, however, depend on the specific alloy involved; those alloys containing copper or zinc are much more susceptible to corrosion. In general, when aluminum is exposed outdoors, it undergoes uniform corrosion. Some corrosion products that have been identified on corroded outdoor aluminum are listed in Table 7 (Ref 36, 38).

When aluminum is exposed outdoors, its silvery surface gradually dulls as it weathers and forms a gray surface patina. The patina contains the hydrated aluminum oxides (bayerite, gibbsite, boehmite) mixed with dirt and atmospheric pollutants (Ref 36, 38). In a relatively non-polluted outdoor environment, the hydrated aluminum oxide layer helps to protect aluminum against further uniform corrosion, especially if the pH of surface moisture remains in the range of 4 to 9. Exposure to pollutants, however, can cause local corrosion or increase the overall corrosion rate, especially if the pollutants react with aluminum to form soluble aluminum salts. Sulfate ions, for example, react with aluminum to form soluble aluminum sulfates that, if not washed away by rain, slowly transform into insoluble aluminum hydroxide sulfates (e.g., $\text{Al}_x(\text{OH})_y(\text{SO}_4)_z$), which are usually amorphous (Ref 36, 39). Sulfate species are abundant constituents of the corrosion layers on outdoor aluminum, especially in marine and industrial environments (Ref 112). Chloride species are also relatively common in aluminum patinas. They are present as soluble aluminum chlorides (that participate in a corrosion cycle causing pitting unless they are washed away by rain), or else they become incorporated into the corrosion layer as insoluble aluminum chloride hydroxides (e.g., $\text{Al}_x(\text{Cl})_y(\text{OH})_z$) (Ref 36). Small spots of local corrosion on aluminum usually signal pitting corrosion, caused by the surface becoming contaminated by chloride ions.

Gold (Gilding). The gilding of outdoor statuary and exterior architectural ornaments (such as domes on churches and government buildings) goes back hundreds of years (Ref 113). Some gilded bronzes have survived since antiquity, such as the four fire-gilded bronze horses from the Basilica of St. Mark in Venice and the bronze statue of *Marcus Aurelius* in Rome, gilded by burnishing gold leaf directly onto the surface (Ref 2, 114, 115). Many of the lead garden sculptures at Versailles (built in the 1680s) in France were originally gilded, although the gilding has now been lost. A gilded lead statue

that did not survive was that of *King George III* in New York City (unveiled in 1770), which, in 1776, was pulled down and broken up so the lead could be turned into bullets (Ref 52). Today, the most common gilding technique is oil gilding (sheets of gold leaf, less than 1 μm , or 0.04 mil, thick, are adhered to the metal surface using a traditional oil size or a modern adhesive), which allows any metal surface to be gilded (Ref 113). Other examples include the gilded lead in the *Albert Memorial* (1876) in London, the gilded bronze in the *Sherman Monument* (1903) in New York City, and the gilded copper in *Quadriga* (1905) in St. Paul, Minnesota (Ref 116–118).

When inappropriate techniques or primers are used to gild metal surfaces for exterior use, the gilding layer can fail within a few years (Ref 113, 117). This is especially true if galvanic corrosion results from the direct contact between the gold and the underlying metal. As the more anodic base metal corrodes, the corrosion products lift and detach the gilding. When traditional gilding approaches are used, corrosion of the underlying metal is minimized, and the gilding can last for several decades outdoors (Ref 113, 117). The traditional approach to gilding metals for exterior use is to apply a primer (either red lead or zinc chromate) to the underlying metal (prior to applying the size and gilding) to minimize corrosion and provide a solid barrier between the

Fig. 6 The pyramidal cast aluminum cap (14.2 cm, or 5.6 in., square at base; 22.6 cm, or 8.9 in., high) at the apex of the Washington Monument in Washington, D.C., set in place in 1884 and exposed outdoors for 115 years. The darker area shows a region where a gold-plated collar (temporarily removed) serves as a lightning protection system. Courtesy of Judith M. Jacob, National Park Service. Photograph 1999

gold and the underlying metal (Ref 113, 117). Because government regulations are restricting the use of these traditional primers in many countries, new primers are needed, and testing is currently underway to find acceptable replacements (Ref 113).

Preservation Strategies

Whether an artifact is a newly commissioned work of art or one that has been outdoors for many years, it must be cared for. The responsibility belongs to local governments, public and private museums, corporations, or private owners. It must be recognized that maintenance will always be required, that maintenance requires adequate funding, and that lack of maintenance funding will result in neglected artifacts. Furthermore, it is highly recommended that a conservator be consulted when artifacts are newly commissioned or acquired, or already exist but have not been receiving maintenance. Conservators can help identify potential problems and prevent inappropriate (but well-intentioned) attempts to care for artifacts that can damage detailed surfaces and patinas (Ref 102).

It is difficult for a single person to make all the decisions about the conservation, degree of intervention, and requirements for long-term care of an outdoor artifact. Conservators often participate in a multidisciplinary approach to making decisions about one or more outdoor artifacts; such an approach involves the participation of several people with different backgrounds, experience, and knowledge (Ref 102, 119). Depending on the artifacts, this may involve one or more conservators, artists, art historians, curators, fabricators, foundry personnel, past users (of heritage artifacts), local administrators, architects, and engineers.

There is now an increasing public awareness of the need for the preservation of outdoor sculptures, thanks to the Save Outdoor Sculpture! program of Heritage Preservation (www.heritagepreservation.org) that was established in 1989 to develop a national inventory of outdoor sculpture in the United States (Ref 102). The information is stored in the Smithsonian's Inventory of American Sculpture (www.siris.si.edu). Similar programs intended to inventory and preserve outdoor sculpture have been established in other countries.

Preserving Heritage Objects. It can be difficult to maintain an artifact and ensure its stability when it is located in an uncontrolled outdoor environment. An artifact may be so important that any additional corrosion due to outdoor exposure is deemed unacceptable, and a decision is made to move the artifact indoors where the conditions can be better controlled. Such a decision was made with the four gilded bronze horses from the Basilica of St. Mark in Venice; the originals were moved indoors, and reproductions were placed outside (Ref 114).

Applying a protective coating (and then maintaining it) is one of the best ways to protect

metal artifacts from corroding in an uncontrolled environment and preserve them for future generations. Of course, certain monuments can be too large or too inaccessible to be coated. The *Statue of Liberty*, for example, remains uncoated and should last for at least 1000 years, assuming the copper corrosion rate remains the same as for the first 100 years (Ref 25).

Conservation. Conservators look for an approach that involves the least possible intervention needed to preserve the artifact and safeguard it for the future. They respect the historical value and past history of the artifact, and try to preserve an artist's original intent by keeping as much original material as possible and, by using techniques that minimize damage to the historic surface, respect the aesthetic qualities of works of art, and are reversible where possible.

Formulation of a conservation treatment begins with conservators examining and documenting the condition of an artifact and, where appropriate, putting forward a treatment proposal. If the treatment proposal is accepted, then conservators carry out the treatment, often with necessary modifications as the treatment proceeds. Before and during the treatment of an outdoor artifact, as much information as possible is researched and recorded (Ref 51). The information collected may include any of the following:

- Object description, location, identification number
- Line drawings, photographs, x-radiographs
- Examination details (e.g., structure, corrosion, associated material)
- Condition before treatment (e.g., evidence of active corrosion)
- Results of any technical analysis (e.g., analysis of metal, repair materials, corrosion products)
- Results of any historical research (e.g., original photographs, technical information)
- Treatment details
- Information from a living artist or research about the artistic intent
- Recommendations for long-term care

Technical analysis and historical research are often required to achieve an understanding of the original aesthetics of the piece (Ref 102). Whenever possible, conservators choose reversible coating materials that can be removed and replaced in the future. When developing a treatment plan for an outdoor artifact, the conservator takes into account the following factors:

- Type of metal, its condition, and the degree of corrosion
- Need to preserve surface details
- Expectations of the owner
- Aesthetics and respect for artist's original intent
- Presence of hazardous materials (e.g., lead paint, asbestos insulation)
- Object location

- Availability of equipment, materials, and funding
- Future maintenance, including maintainability of paint or coating

Repair and Restoration (Reconstruction).

Although the main intent of conservation is to preserve the artifact and prevent it from suffering further damage, a heritage object may have deteriorated, and a decision is made for additional intervention. This can involve the repair of damaged parts or the replacement of missing pieces. This can even involve a certain amount of restoration or reconstruction in order to actually return the artifact to a known earlier state or make repairs to the supporting base to ensure the artifact does not fall off. When repairs are made, galvanic corrosion is avoided by using the same metal as in the artifact or by using nonconductive materials (e.g., mastics, nonconducting polymers, washers, synthetic fluorine-containing resin) to separate different metals (Ref 38). When direct contact between different metals cannot be avoided (such as when replacing a rusting internal armature in a copper alloy sculpture), galvanic corrosion is minimized by replacing the iron with a metal as close as possible in the galvanic series to the copper alloy. For example, the corroded wrought iron armature in the *Statue of Liberty* was replaced with type 316L (S31603) stainless steel (Ref 25).

Regular inspections of both an artifact and its immediate surroundings (recommended at least annually) are extremely important to the life expectancy of the artifact, because they allow problems to be identified, regular maintenance to be carried out, and follow-up action to be initiated. During regular inspections, accumulated garbage, leaves, and nests can be removed. Trees can be trimmed and local vegetation cut back to allow for good air circulation and to deter birds. The base of monuments can be checked to see if power mowers have damaged them, if water sprinklers are regularly spraying them, or if deicing salts are accumulating because of nearby use. The artifact can be washed with mild soap and water to remove accumulated dirt, salts, pollution, and bird droppings. Graffiti can be removed and damage identified (and arrangements made for its repair). Reapplication of a wax coating or repair to minor paint flaws can be made. Finally, determination can be made whether any follow-up treatment needs to be carried out.

More frequent inspections will also help in the rapid identification of problems. If, for example, the staff is taught about local cultural artifacts, factors contributing to corrosion and deterioration, conservation, and regular maintenance, then they can participate in the long-term preservation of these artifacts. They can keep a watchful eye on artifacts when working in the vicinity, and they can report any new damage (e.g., vandalism) to an appropriate person so the problem can be addressed as soon as possible.

Conservation Strategies for Specific Metals

In this section, conservation strategies are addressed for the five common metals used in outdoor artifacts: copper alloys, iron alloys, zinc, lead, and aluminum. A brief discussion of gold (gilding) is also included.

Copper Alloys. Most outdoor bronze statues are colored using chemicals to produce an artificial patination, and they are often coated, usually with a wax, before they are placed outdoors (Ref 79). If a sculpture is well maintained, all it needs is regular cleaning to remove soluble material and regular reapplication of a coating. If, on the other hand, bronze sculptures are left outdoors without maintenance, any coating or patina eventually breaks down or wears off, often unevenly. The surface of neglected bronze statuary, after decades of outdoor exposure, becomes covered with copper corrosion products along with dirt, bird droppings, and other debris. Its appearance is disfigured, often patchy and streaked with areas of alternating black and light green (Ref 7, 28, 84). The contrasting light and dark areas obscure the overall sculptural details. The overall approach to the conservation of a neglected and corroded bronze statue is to clean it and then protect it from corrosion with a coating of wax or lacquer (Ref 42, 84, 102, 120, 121). Figure 7 contains an example of the appearance of the bronze statue of Rodin's *The Thinker* before (Fig. 7a) and after (Fig. 7b) receiving conservation treatment. In addition to cleaning and coating, other areas that may need attention include structural repairs, securing supports to the base, replacement of rusting internal armatures or bolts, repairing cracks, replacing lost parts, clearing existing weep holes (or drilling new ones), and repatination.

Cleaning. Conservators have developed a wide range of methods for cleaning corroded bronzes (Ref 122). The first step in removing pollutants, dust, bird droppings, and other surface debris is washing with an anionic or non-ionic detergent in tap water, using sponges or soft brushes, and followed by thorough rinsing (Ref 42, 120). Many conservators favor this step as the minimum intervention necessary (Ref 42, 85, 122). If conservators (or others) decide further intervention is needed, then other cleaning techniques are available. However, additional cleaning, especially those methods involving pressure, must be done with caution to avoid damaging the fine detail in artifacts and to minimize the cumulative loss of detail from repeated corrosion removal. The intent of cleaning is usually to even out the patina (by removing the superficial corrosion products but leaving firmly adhered ones) rather than removing all of the patina and exposing bare metal (Ref 84). Solvent cleaning, low-pressure steam cleaning, or blast cleaning with ice or dry ice (frozen CO₂) can be used to remove old coatings (Ref 102). Mechanical cleaning (e.g., fine bronze wool, synthetic abrasive pads) or

blast cleaning with soft media (e.g., plastic beads, corncob granules, nut shells) at low pressure can also be used to remove nonadherent material, hard deposits, and some surface corrosion products (Ref 85, 120, 123). Medium-pressure washing can also be used to remove some surface corrosion and readily soluble material (Ref 119, 124).

Repatination may be necessary if the original patina is gone. This may involve repatinating the entire surface or just selectively patinating small areas to visually integrate the color. Repatination is usually carried out using various chemicals to achieve the desired color (Ref 79). Under certain circumstances, the color is altered with pigmented waxes rather than with chemicals. Recipes for green patinas often contain sulfate and chloride ions, and recipes for darker-brown patinas often contain sulfide ions (Ref 79). Many conservators avoid using recipes that contain chloride ions to avoid the possibility of future corrosion problems.

Coating. After cleaning bronze statuary, a protective layer of wax or lacquer is usually applied. Coatings seem to adhere better to a bronze surface after some of the corrosion products have been removed (Ref 84, 85). Conservators sometimes apply benzotriazole, a copper corrosion inhibitor, to the bronze surface before applying a coating, although this may slightly darken the patina, and its effectiveness may be limited (Ref 120, 125). Once the bronze has been coated, it is important that an ongoing program is established to maintain the coating (Ref 126).

Waxes are the most popular coatings used on outdoor bronzes (Ref 120), and they have proven effective in protecting outdoor bronzes from corrosion, as long as the coating is well maintained (Ref 85). Wax coatings usually consist of various mixtures of petroleum-based (e.g., microcrystalline wax) and synthetic (e.g., polyethylene) waxes, although conservators sometimes use commercial paste waxes (Ref 85, 120). In the past, beeswax, lanolin, and other natural-product waxes were used, but today, these are rarely used because of their tendency to form metal soaps from the reaction between the underlying metal and the free fatty acids in the wax (Ref 127). When the wax coating is applied to either a heated (Ref 128) or a cold metal surface, it usually saturates the light-green areas and darkens the overall color, making it easier to read the sculptural form (Ref 42, 85). Waxes are usually reapplied once a year (Ref 85, 120). Old coatings that have become dirty are often cleaned with mineral spirits before more wax is applied (Ref 85). Old waxes are difficult to remove but can often be removed with solvents, steam, or low-pressure blast cleaning (Ref 85, 102). Recently, electrochemical impedance measurements have been used to evaluate various commercial waxes and coatings for possible use on outdoor bronzes (Ref 129–133).

Lacquers have also been used on outdoor bronzes, although, because they tend to be brittle, they are not used on sculptures that the public

climbs on. The most popular lacquer is Incralac, which contains the acrylic Acryloid (or Paraloid, Rohm and Haas Co.) B-44 (Ref 102, 120). Conservators are now using thickness gages and perforation detectors to maintain quality control

(a)

(b)

during lacquer applications, although it can be difficult to measure coating thickness on a heavily textured sculpture (Ref 134). Sometimes, a wax is applied over the lacquer. Lacquer needs regular touchup and periodic replacement, ranging anywhere from 2 to 10 years (Ref 84, 102, 120). Removal of an old Inralac coating is difficult because of its tendency to cross link as it ages (Ref 135). Research is currently underway to identify better clear coatings (ones with good adhesion and good reversibility) for protecting outdoor bronze sculptures (Ref 136–141).

Iron Alloys. Most outdoor artifacts made from iron alloys are protected from corrosion with paint or some other protective coating. Others are left uncoated because they are corrosion resistant (stainless steel art) or they are intended to develop a natural rust-colored patina (weathering steel). Many industrial and military artifacts come painted and well maintained when they are decommissioned and turned into a monument, but others can be seriously rusted and deteriorated when they receive their heritage designation.

Repairs. Although conservators try to save as much original material as possible, they often need to replace missing or severely deteriorated parts (Ref 51, 52). To prevent water from penetrating and being retained in the interior of hollow areas, such as in cast iron balustrades, cracks are repaired (Ref 51, 58). Welding can be used to repair cracks in wrought iron and, under certain conditions, in cast iron as well (Ref 51, 58). Fillers, such as epoxy resins (metal-filled ones) or polyester-based autobody putties, are used to fill small defects and casting flaws (Ref 51, 58).

Cleaning. Uncoated, polished stainless steel sculptures (especially ones sheltered from regular washing by rain) and well-maintained coated iron surfaces all benefit from regular cleaning with a mild detergent and warm water to remove dirt, grease, pollutants, salts, and other accumulated material (Ref 52, 58).

When a coated iron surface is not maintained and the coating has failed to such an extent that serious rusting has become a problem, then the iron is cleaned and a protective coating applied (Ref 142). In the case of historic fences and other architectural pieces, the iron is usually cleaned to bare metal and repainted. For industrial artifacts, it may only be necessary to remove loose surface material and then coat with a wax or a corrosion-prevention product. Old paint is tested before it is removed to determine if it contains lead; stringent safety precautions are needed when removing lead paint to avoid lead poisoning. Hazardous dust and waste must be contained, and all contaminated material must be properly disposed of according to local regulations (Ref 92). Although lead-containing paints are now banned in many countries, red lead was used in the past as an effective corrosion-inhibiting primer on iron, and white lead was used as a pigment in exterior paints.

When an iron surface is to be painted, the standard approach to surface preparation is to remove all dirt, grease, old paint, and existing

rust, either by chemical (e.g., phosphoric acid, paint strippers) or mechanical (e.g., abrasive blasting) methods (Ref 52, 58, 142). The drawback with using chemicals (including water) in situ is that they penetrate into hollow interiors, and residues are difficult to fully remove (Ref 58). Chemical removal of rust or paint is usually limited to artifacts that can be fully disassembled, cleaned, rinsed, and reassembled. When abrasive blasting methods are used, various media are tested, starting with the least damaging (i.e., soft abrasives and low pressures), to determine the most appropriate method for removing surface material without damaging (e.g., pitting the surface or perforating the metal) the underlying historic metal. Dry abrasive blasting methods have been used to clean old paint and surface rust from cast and wrought iron artifacts such as fountains, historic fences, and other architectural elements (Ref 51, 58, 143). Wet abrasive blast cleaning is generally not used because of the problem of rapid flash rusting (Ref 58). However, wet-cleaning methods are essential for removing soluble sulfate-containing and chloride-containing contaminants from an iron surface (Ref 51, 144). If these soluble salts are not removed prior to painting, then early paint failure will result (Ref 144).

Another approach to preparing a rusted iron surface for painting is to remove all dirt, grease, and loose material, including loose rust, but leave the existing adherent rust. This rusted surface is then coated with a rust converter primer prior to painting (Ref 69, 145). Rust converters contain a polymeric component (that accepts a topcoat of a compatible paint) and tannic acid (that reacts with rust to form a blue-black iron(III) tannate film) (Ref 145).

Painting iron and steel is the most common and effective method of controlling rusting, and surface preparation is the key to effective paint adhesion (Ref 102). Also important are using a compatible paint system and following manufacturer instructions (Ref 52). Once the iron surface has been suitably cleaned (including removal of contaminating chloride ions) and prepared for painting, it is primed and then topcoated with a compatible paint system. A number of different primers and paints have been used on historic outdoor iron (Ref 51, 52, 58, 143, 144). Alkyd paints are popular because they have proven effective and are relatively easy to maintain (Ref 51).

Waxlike Coatings. The application of a wax or some other corrosion-prevention coating is another method used to control rusting on outdoor iron and steel. With these coatings, it is not necessary to strip off existing rust or paint, only clean by removing dirt, grease, and loose material such as flaking paint and nonadherent rust. Abrasive blasting with soft organic abrasives has proved successful (Ref 92). Wax mixtures, such as those used on outdoor bronzes, have been used on rusted outdoor iron (Ref 70). Commercial corrosion-prevention or rust-preventive products have also been used. Corrosion-prevention products are petroleum-based, and they dry by

solvent evaporation, leaving a film (often waxlike) that can provide temporary corrosion protection to outdoor metals. They have been used to protect military monuments (Ref 72), industrial machinery (Ref 92), and cast iron cannons (Ref 146).

Zinc. The problems generally encountered on outdoor architectural and sculptural zinc are largely structural. After years of outdoor exposure without maintenance, the coating fails, and the underlying metal corrodes. Because zinc sculptures were often assembled by soft soldering smaller pieces together, the exposed surfaces can become disfigured, with criss-crossing solder joints standing in relief above the corroded zinc (Ref 56, 61). Frequently encountered on corroded zinc are defective foundry joints, disfiguring repairs, corroded wrought iron armatures, corrosion due to water trapped by concrete in the core, fractures in large zinc pieces unable to support themselves, breakage, and casting flaws (Ref 51).

Conservation of zinc sculptures often involves dismantling them, removing any core material or rusting armatures, and cleaning the surface with relatively neutral solutions (neutral detergents, noncaustic degreasing agents, noncaustic paint strippers) or by using (with extreme caution) low-pressure abrasive blasting with a suitable media soft organic material (Ref 51, 56, 57, 61). Structural repairs are made by soft soldering, welding, or using polyester or epoxy resins reinforced by fiberglass (Ref 52, 56, 57). Corroded wrought iron armatures are usually replaced with stainless steel ones and isolated from the zinc to avoid galvanic corrosion problems (Ref 56, 57). Protective coatings are often applied, but they are dependent on the nature of the original and existing surfaces (Ref 102). Some zinc pieces are left uncoated (especially if they were originally uncoated), some are repainted to resemble the original color, and some are given a protective clear coating of wax or lacquer (Ref 56, 147, 148). It is important to ensure that the intended paint system (especially the primer) has been specifically designed for a zinc surface (whether it is zinc metal, galvanized steel, or a surface covered with a zinc-rich primer). Alkyd or oil-based paints are avoided because zinc soaps form at the interface between the metal and the paint (because zinc reacts with fatty acids in the paint), cause poor adhesion of the paint system, and quite quickly result in peeling paint.

Lead suffers mechanical breakdown with tearing, buckling, and fatigue cracking (Ref 52). Large lead castings of sculpture, garden ornaments, or fountains cannot support themselves; support is provided by leaving the internal core material (plaster and sand) and using wrought iron armatures (Ref 66, 149). Unfortunately, large lead objects often sag or become distorted, because lead is heavy and subject to creep. Ingress of water into the core material or through cracks or porosity in the lead casting causes corrosion of the inner lead surface and rusting of the iron armature (Ref 51). Rusting of the iron

armature will cause further cracking of the lead as well as staining.

For outdoor lead, the basic cleaning, coating, and cyclical maintenance strategies for lead are similar to those for bronze (Ref 102). Periodic removal of dirt and corrosive bird droppings is done by washing with a neutral-pH soap in warm water with light brushing (Ref 51). White corrosion (lead carbonate hydroxide) is sometimes removed using a chelating agent such as ethylenediamine tetraacetic acid (Ref 51, 150). Repairs to cracks, tears, and loss are done by lead burning (welding) rather than soldering (Ref 51). Removal of old paint and corrosion products from the surface of lead is done with great care, especially if mechanical methods are used, because lead is soft and easily damaged (Ref 102). Abrasive blasting techniques are avoided for this reason and because they generate toxic lead dust (Ref 51). Corroded wrought iron armatures are replaced with stainless steel ones, a process that usually requires disassembly of the sculpture (Ref 102). To ensure all surfaces receive sufficient support, some conservators fill repaired lead sculptures with closed-cell polyurethane foam, despite the drawback that this foam will be difficult to remove in the future (Ref 51). Lead sculptures can be repainted (if they were originally painted), coated with a protective layer of wax, or left uncoated (Ref 51, 66).

Aluminum. Uncoated and anodized aluminum benefit from regular cleaning to remove airborne deposits, especially chloride ions. Cleaning is usually done with gentle cleaning solutions such as neutral detergents (Ref 151). Aluminum should not be cleaned with strong cleaners such as acids ($\text{pH} < 4$), alkaline solutions ($\text{pH} > 9$), or chlorinated solvents (Ref 151). Unpainted aluminum and anodized aluminum should be washed regularly (every 1 to 12 months), with the greatest frequency of cleaning in industrial and marine atmospheres and where surfaces are not washed by rain (Ref 151, 152). The least cleaning is needed in rural environments.

The surface oxide on aluminum is relatively thin and easily scratched or damaged by abrasives. Aluminum should be cleaned with nylon brushes, not with steel or brass wool because residual metal fragments will promote galvanic corrosion (Ref 152). When dealing with historic aircraft on exhibit outdoors, regular maintenance, inspection, and repair combined with good ventilation to the interior are needed (Ref 153). A transparent coating will help maintain aluminum that has been finished with a highly reflective surface (Ref 102). When aluminum is painted, the coating needs to be maintained, and certain coatings (e.g., powdered coatings) may be more difficult to maintain than others.

An example of the conservation of an outdoor cast aluminum sculpture (95%Al–2.5%Cu–2.5%Zn) can be found with a figure of *Eros* (Fig. 8) unveiled in Liverpool, England, in 1932 (Ref 154). It had not held up well to outdoor exposure (Ref 110). Over time, the surface became covered with an encrustation of calcium

sulfate that had leached from the interior, through metal found to be quite porous. The surface had also been damaged by vandalism and stained with iron corrosion caused by rusting of the internal iron armature. The sculpture has now been moved indoors and the surface encrustation removed, using laser cleaning (Fig. 9) (Ref 110, 155).

Gold (Gilding). Gilded metals have a limited lifetime when exposed outdoors, and regilding is necessary every few decades (Ref 117, 119). This lifetime, however, may be less than a year if the gilding is not done properly or if inappropriate materials are used (Ref 113). It is difficult to implement maintenance for gilded architectural elements, especially domes on churches. Gilded statues, on the other hand, benefit from annual maintenance that can include washing (to remove airborne dirt, salts, and pollutants), local repair of gilding loss, and replenishing of any wax coating if applied (Ref 117).

New Commissions

Another aspect of outdoor artifacts is dealing with new installations, either new commissioned works of art or heritage artifacts no longer in service. The new owner, whether a government or private organization, needs to work with various professionals (conservators, curators, site engineers, architects, the artist, the fabricator, the

previous owner) to ensure the new piece can survive outdoors with a minimum of future damage and corrosion problems (Ref 156, 157). It is important that a conservator be consulted to carry out a technical review of the artist's proposals as well as look at site locations to help identify potential problems and make recommendations about maintenance (Ref 158). If an artifact is located at a site where it is easy to maintain, then the chances are good that it will be maintained. The following aspects should be considered when dealing with new commissions:

- Are the materials corrosion resistant?
- Is there potential for galvanic corrosion (are two metals in direct contact)?
- Do both the site and design allow for good water drainage?
- Is the site clear of harmful trees and other vegetation?
- Have all public safety issues been addressed?
- Is the site remote, or will it invite vandalism?
- Is there a rapid response plan for vandalism?
- Are attachment points covered or made tamperproof?
- Can weak areas be reinforced to make them harder to bend or steal?
- Has a maintenance program been recommended?
- Are there funds to implement the maintenance program?
- How easily can the site be accessed for maintenance?

Many communities have legislation requiring a percentage of public construction funds be spent on art in public places, with a provision that part of this money be put aside for future maintenance (Ref 102). In other places, maintenance programs are developed and budgeted for at the time of acquisition. It is hoped that future problems with new commissions (or with newly designated heritage artifacts) can be avoided with the help of the conservation profession, which can identify potential problems and suggest design improvements, including the selection of materials that are durable in an outdoor environment.

Corrosion of Metal Artifacts in Buried Environments

Lyndsie S. Selwyn, Canadian Conservation Institute

HUMANS BEGAN USING METALS thousands of years ago to make functional objects such as spear points and rudimentary tools, ornamental objects, and objects of spiritual significance. Metal artifacts from various periods have become buried in underwater locations or in the ground because they were lost, abandoned, or sacrificed. Metal artifacts are often recovered from carefully excavated archaeological sites, while others are discovered by accident as a result of farm work or the construction of roads, railroads, or new buildings (Ref 1). In marine environments, metal artifacts are usually associated with historic shipwrecks located in coastal waters and along maritime trade routes (Ref 2).

The corrosion processes of metals during burial are complex, being affected by environmental pollutants, other archaeological material, geography, microorganisms in the soil, vegetation, land use, soil chemistry, soil physical properties, and the presence or absence of water and air (Ref 3). The burial environment can range from soil through which groundwater flows freely, to seawater with high salt concentrations, or to a polluted harbor contaminated by foul-smelling hydrogen sulfide. The corrosion rate of buried metals is extremely variable, ranging from rapid to negligible, depending on both the metal and its burial environment. During burial, corrosion can penetrate deep into a metal and weaken it, making it extremely fragile and subject to damage during and after excavation. Some objects may be totally corroded and others may still contain a substantial metal core.

Archaeologists use buried cultural artifacts to learn about the past. They need to know the shape of the object in order to recognize its function or interpret its use. The shape of excavated archaeological artifacts is often obscured by corrosion products and other material from the burial environment. Archaeological conservators use various techniques to assist in identifying the original shape of artifacts and to avoid deterioration and possible disintegration after excavation by minimizing further corrosion (e.g., using controlled environmental conditions, carrying out appropriate conservation

treatments). Many excavated archaeological artifacts are now preserved within museums and other cultural institutions. Unfortunately, there are also untreated archaeological artifacts that are stored in uncontrolled conditions and are continuing to corrode (particularly iron) because of lack of funds for better storage or for conservation treatments (Ref 4).

The Burial Environment

Artifacts are found buried in soils that can be relatively dry, damp, intermittently wet, or permanently water saturated, or they are found submerged under water in lakes or the ocean (Ref 5). They can be exposed to the atmosphere and surface-weathering processes, or they can be deposited onto lake, estuarine, or marine sediments and eventually become buried within these sediments. Natural burial environments vary from oxidizing to reducing and from acidic to alkaline (Ref 6). If the burial environment changes, corrosion processes and corrosion products can also change. The key environmental variables that affect the corrosion of buried metal artifacts are water (including dissolved salts and gases), sulfate-reducing bacteria, pH (acidity), and potential (oxidizing or reducing capacity) (Ref 7).

Water. The corrosion of buried metal artifacts is electrochemical; water is the electrolyte, and dissolved species (salts, gases) affect the corrosion rate. The amount of water available can range from water vapor at various relative humidities to fluid water under immersed conditions (Ref 8). When metal artifacts sink to the bottom of rivers, lakes, harbors, or the ocean, they are surrounded by water and may become partially or completely buried in sediment. When metal artifacts are buried in soils, they can be located below the water table, where the soil particles are completely surrounded by water, or they can be buried above the water table, where the space between soil particles is filled with moist air and other gases (Ref 9). Variations in the water table can further complicate the corrosion process of metal artifacts. Above the

water table, the compactness and water content of soils are important; clays retain moisture within capillaries, whereas sandy soils drain quickly (Ref 8).

Dissolved salts increase the conductivity of water (lower the soil resistivity) and accelerate electrochemical reactions (Ref 9). Consequently, metal artifacts generally corrode faster in water containing high concentrations of dissolved salts; the corrosion rate can, however, become lower if metals react with soluble salts to form an insoluble protective layer. Soluble salts are present in groundwater, lakes, and oceans. The concentration of these dissolved salts is lowest in freshwaters, higher in harbors and coastal waters, higher still in open seawater, and highest in enclosed seas (Red Sea, Mediterranean) that are subject to a high rate of evaporation (Ref 10). Soil solutions associated with calcareous (limestone, dolomite) soils are high in magnesium, calcium, and carbonate ions (Ref 8). In relatively arid regions, the net direction of water movement is upward, and evaporation at the soil surface results in the precipitation of salts containing various cations (e.g., sodium, potassium, magnesium, calcium) and anions (e.g., carbonates, chlorides, sulfates) (Ref 5, 9). Artifacts buried in arid regions are likely to be encrusted with salts, and the surface corrosion products are likely to be metal carbonates and sulfates (Ref 5). In seawater, the major ionic constituents (listed in decreasing order of relative amounts) are chloride, sodium, sulfate, magnesium, calcium, and potassium (Ref 11).

The salts in soil can be markedly altered by human activities such as industrialization, modern agriculture, and changes in land use (Ref 3, 8). The modern burial environment changes as surface soils accumulate a wide range of salts from phosphate fertilizers, waste (human, animal, industrial), deicing salts, weed-killing chemicals, bones, wood ash, and atmospheric pollution (Ref 1, 12). In Sweden, for example, recently excavated bronzes are more deteriorated than earlier finds in the same region (Ref 3). This increased deterioration is attributed to increased atmospheric pollution and acid rain (especially from the Continent and Great Britain) and

proximity to roads where deicing salts are used (Ref 3, 13).

Dissolved Gases. Oxygen and carbon dioxide are the principal dissolved gases in surface waters, and they are derived from the atmosphere, biological activity, and the decomposition of organic material. The solubility of these gases decreases with increasing temperature (Ref 14).

Oxygen. Reduction of dissolved oxygen gas is a common cathodic reaction contributing to the corrosion of buried metals (particularly for pH 4 to 9). Metals are more likely to be heavily corroded in aerated damp environments than in low-oxygen environments (with no microbial activity), where the metals are more likely to be covered with only superficial corrosion. Surface waters exposed to the atmosphere generally become saturated with oxygen (solubility $2.7 \times 10^{-4} M$) because of local turbulence and where oxygen is released by photosynthesis (Ref 5, 12). In soils where the diffusion of air is restricted, oxygen gas is only slowly incorporated into water. Low oxygen levels exist in stagnant, waterlogged soils (clay, peat bogs) and under marine sediments and concretions. These conditions tend to be the least corrosive to buried metal artifacts, although a corrosive environment may develop under anaerobic conditions if sulfate-reducing bacteria are active (Ref 1, 3, 15). A bronze spearhead, for example, remained well preserved, with the detailed surface still evident, after 3000 years buried in the tidal mud of a river bed in England (Ref 1).

Carbon dioxide (solubility $1.1 \times 10^{-5} M$) dissolves in water to produce carbonic acid, H_2CO_3 (Ref 5). Carbon dioxide gas is introduced into water through the dissolution of atmospheric CO_2 and by the aerobic decay of organic matter. Biological activity (supported by sufficient nutrients) removes oxygen and generates carbon dioxide (Ref 9). When the only source of carbon dioxide is atmospheric (e.g., from rainwater), then the water is slightly acidic (pH 5.6). When carbon dioxide is also being generated by the microbial breakdown of organic matter, then the concentration of dissolved carbon dioxide is increased, and the pH becomes more acidic (e.g., pH 4.9) (Ref 5). Seawater is kept in the pH range of 7.5 to 8.3 by the buffering action of the bicarbonate (HCO_3^-)-carbonate (CO_3^{2-}) equilibrium (Ref 14).

Sulfate-Reducing Bacteria (SRB). Buried metals are affected by SRB growing on a metal surface or nearby. These bacteria grow in near-neutral, anaerobic environments containing a source of sulfate ions, such as decomposing organic matter (Ref 15). Sulfate-reducing bacteria grow in waterlogged soils; in mud at the bottom of rivers, lakes, marshes, and estuaries; and under deposits on metals in freshwater and seawater (Ref 15). When SRB grow on a metal surface, they consume hydrogen atoms produced at cathodic sites and reduce sulfate (SO_4^{2-}) ions to sulfide (S^{2-}) ions (Ref 15, 16). If SRB are located on a metal surface, then the sulfide ions react directly with metal ions to form metal

sulfides (Ref 16). If SRB are located in close proximity to metals, then the sulfide ions dissolve as HS^- (above approximately pH 7) or H_2S (below approximately pH 7) and diffuse to the metal surface (Ref 17). In marine sediments, the maximum SRB populations are typically located to a depth of approximately 50 cm (20 in.), although SRB can be located at greater depths if decaying organic material is present, such as wooden hulls of shipwrecks (Ref 14). Under certain conditions, SRB remain inactive despite favorable growing conditions. Well-preserved iron, including 2000 year old Roman artifacts, was recovered from such a site in York, England (Ref 18). The inactivity of the SRB was attributed to tannins in the soil (Ref 1).

The best known SRB are the genus *Desulfovibrio*, which thrive at a pH of 4 to 8 and temperatures between 10 and 40 °C (50 and 105 °F) (Ref 15, 16). Active growth of SRB contributes to corrosion on aluminum, copper alloys, iron and steel, stainless steels, and zinc. The corrosion rate can be accelerated by the formation of local deposits of metal sulfides, which generally have good electrical conductivity (Ref 19). Pitting can result when a discontinuous sulfide film is present, because of the galvanic effect created by contact between the cathodic film and the underlying anodic metal (Ref 9, 15). On the other hand, a protective film can also form if the sulfide forms as a continuous, adherent layer over the entire metal surface (Ref 19, 20).

The pH of most environments encountered in nature falls between 4 and 9, although certain environments can have a lower or higher pH (Ref 9, 21). In general, alkaline soils are benign to metals, and acid soils are aggressive (Ref 1). Certain metals, such as aluminum, lead, and zinc, are amphoteric and can experience an increased corrosion rate in both acidic and alkaline conditions (Ref 22).

Acidic environments (pH < 7) develop where organic material is decomposing and large quantities of organic acids are produced (Ref 6, 12). Rainwater, waterlogged soils, and bogs are typically acidic (pH 3 to 6) (Ref 5). In climates where the drainage of water is downward through the soil profile, the environment becomes acidic from the leaching of cations (calcium, magnesium, sodium, potassium) from soil minerals (Ref 5, 9, 12). An acidic environment encourages the oxidation of metals and the dissolution of corrosion products.

Alkaline environments (pH > 7) develop because of the dissolution of inorganic compounds, especially in regions where evaporation exceeds precipitation (Ref 5, 6). Soils containing groundwater that has flowed over limestone are alkaline because of the dissolution of calcium carbonate (Ref 9). In regions where there are calcareous rocks, the soil has good buffering capacity against acidic deposition (Ref 3). The pH of seawater normally falls in the slightly alkaline range between 7.5 and 8.3 (pH > 8 in surface seawater) because of the buffering action of the bicarbonate-carbonate equilibrium (Ref 10, 14). The pH in marine sediment may

drop to 7.0 because of the dissolution of hydrogen sulfide produced by SRB.

Potential. The electrode potential (oxidation-reduction potential) of a burial environment is the potential of an inert electrode, such as platinum, placed in that environment and measured with respect to a reference electrode. The measured potential is not a measure of the oxygen concentration but is an indication of the oxidizing or reducing capacity of that environment (Ref 9). When the potential becomes more positive, the conditions are more oxidizing and vice versa (Ref 1). Natural environments can be oxidizing (i.e., able to accept electrons), reducing (i.e., able to donate electrons), or neutral (Ref 5, 23).

Oxidizing environments are typically oxygen rich because they are in contact with the atmosphere, whether by easy access of air (e.g., sandy soils) or by the penetration of water containing dissolved oxygen (e.g., tidal zone, strong wave action) (Ref 6, 24). Reducing environments are oxygen poor. They develop in waterlogged soils, poorly drained swamps, under clay or tightly packed sediment, and under marine concretions where stagnant conditions restrict the replenishment of dissolved oxygen (Ref 6, 24).

Under reducing conditions, SRB activity can cause damage to buried metals (Ref 9, 25). Table 1 lists four ranges of electrode potential (on the standard hydrogen electrode, or SHE, scale corrected to pH 7), categorized according to the corrosivity of burial environments containing SRB (Ref 9, 15, 25). Above 400 mV, the environment is oxidizing and does not support SRB.

Potential versus pH Diagrams for Environments in Nature. One approach to characterizing natural environments is to measure their electrode potential and their pH and then determine which of four general categories they fall into: oxidizing and acidic, oxidizing and alkaline, reducing and acidic, and reducing and alkaline (Ref 22). These categories are shown in Fig. 1 in a diagram of potential versus pH and commonly referred to as a potential-pH or Pourbaix diagram (Ref 23). As mentioned earlier, the pH of most environments in nature falls between 4 and 9. Neutral environments, from an acid-base viewpoint, fall along the vertical dashed line at pH 7.

In natural burial environments under 1 atm pressure, the potential scale is limited by the thermodynamic stability of water (Ref 5, 22).

Table 1 Categories of the corrosivity of burial environments containing sulfate-reducing bacteria according to electrode potential (corrected to pH 7)

Category	Potential, mV (SHE)
Noncorrosive	> 400
Slight	400–200
Moderate	200–100
Severe	< 100

SHE, standard hydrogen electrode

The region where water is stable lies between the two broken lines labeled “A” and “B” in Fig. 1. The upper limit of stability is given by line B, along which the oxygen gas pressure equals 1 atm. If the potential of the system rises above line B, then the pressure of oxygen gas becomes greater than 1 atm, and water is oxidized with the evolution of gaseous oxygen: $2\text{H}_2\text{O} \rightarrow \text{O}_2(\text{g}) + 4\text{H}^+ + 4\text{e}^-$ (Ref 23). The lower limit of stability is given by line A, along which the hydrogen gas pressure equals 1 atm. If the potential of the system falls below line A, then the pressure of hydrogen gas becomes greater than 1 atm, and water is reduced with the evolution of gaseous hydrogen: $2\text{H}_2\text{O} + 2\text{e}^- \rightarrow \text{H}_2(\text{g}) + 2\text{OH}^-$ (Ref 23). Neutral environments, from an oxidation-reduction viewpoint, have potentials that fall along line C, which is where the hydrogen gas partial pressure equals twice the oxygen gas partial pressure (Ref 23). Oxidizing environments have potentials falling between lines B and C. Reducing environments have potentials falling between lines A and C.

Terrestrial Environments. The corrosion of metals in soils is affected by the availability of oxygen, moisture content, dissolved species, soil

conductivity, and biological activity. Soils are complex aggregates of moisture, gases, organic matter, living organisms, precipitated materials, and particles of weathered rock (Ref 8, 9). Sandy soils are almost devoid of organic matter and consist largely of inorganic materials weathered to fairly uniform-sized particles. On the other hand, peat bogs and swamps are primarily water-saturated decaying organic matter mixed with minor amounts of inorganic material (Ref 3). Soils are commonly named according to the general particle size range of inorganic constituents, with, for example, particle diameters being 0.07 to 2 mm (0.003 to 0.08 in.) in sandy soils, 0.005 to 0.07 mm (0.0002 to 0.003 in.) in silts, and less than 0.005 mm (0.0002 in.) in clays (Ref 8).

The aeration of soil is directly related to its pore space and whether this space contains water or moist gases. Water flows quickly through coarse-grained sand, allowing for good drainage and easy access of atmospheric oxygen. Conversely, water has trouble permeating clay soils made up of small particle size (Ref 9). Biological activity tends to decrease the oxygen content and replace the oxygen with gases from metabolic

activity, such as carbon dioxide (Ref 8). Anaerobic conditions develop in soils where large amounts of organic matter are decomposing through biological activity or where stagnant, waterlogged conditions significantly decrease oxygen diffusion (Ref 8).

Marine Environments. The corrosion of metal artifacts in a marine environment is affected by the metal composition, water composition, temperature, marine growth, sediment composition, position of artifacts relative to other materials, depth of burial in sediment, and extent of water movement (Ref 14).

A layer of hard concretion usually encrusts shipwrecks, metal artifacts, and other sunken material located in seawater where organisms grow by photosynthesis (Ref 11, 26). The white concretion is mainly calcium carbonate (calcite, aragonite), and it forms a semipermeable barrier between the artifact and the seawater, decreasing the availability of dissolved oxygen and protecting the artifact from physical damage (mechanical abrasion, wave action) (Ref 14, 26, 27). The concretion is usually the result of encapsulation by marine organisms, mainly those such as corals, coralline algae, tubeworms, and shellfish that leave behind a calcium carbonate skeleton after they die (Ref 11). Metals such as copper and lead that release toxic ions discourage the growth of these marine organisms (Ref 27).

Calcium carbonate can also precipitate directly from seawater, particularly in surface waters that can become supersaturated in calcium carbonate because of the dissolution of atmospheric carbon dioxide. Because the solubility of calcium carbonate decreases with increasing pH, significant amounts can precipitate (as calcite and aragonite) if the pH rises above approximately 9 (Ref 11). Precipitation of calcium carbonate occurs in regions where intense photosynthetic activity increases pH (shallow water) as well as on metal surfaces where the cathodic reaction (typically, reduction of dissolved oxygen) increases the local pH (Ref 11). Concretion formation is sometimes prevented by unusual conditions; for example, no concretions formed on artifacts associated with the *RMS Titanic* (1912), which sank off the coast of Newfoundland to a depth of 4 km (2.5 miles), where the water was cold (1 to 2 °C, or 34 to 36 °F) and the hydrostatic pressure high. Instead of concretion, the iron in the *Titanic* became covered with “rusticles” (formed by bacterial action); the rusticles consisted of iron oxide hydroxides, with lepidocrocite making up the exterior shell, and goethite on the inside (Ref 28).

The conditions within the concretion can be significantly different from the surrounding seawater. The semipermeable nature of the concretion can separate anodic and cathodic reactions. At the metal surface beneath the concretion, the metal ions produced by the anodic reaction undergo hydrolysis and increase the acidity. At the same time, the concentration of chloride ions increases underneath the

Fig. 1 Schematic diagram of potential versus pH showing the various regions found in nature at a total pressure of 1 atm. The limits of stability for water are given by the lower line A, $E = 0.000 - 0.059 \text{ pH}$ (standard hydrogen electrode, or SHE), and the upper line B, $E = 1.228 - 0.059 \text{ pH}$ (SHE). Line C, $E = 0.813 - 0.059 \text{ pH}$ (SHE), separates oxidizing regions from reducing ones. The dashed vertical line at pH 7 separates acidic and alkaline regions. Adapted from Ref 23

concretion, because these negative anions diffuse inward to maintain charge balance with the positive metal cations (Ref 26, 27). The pH can decrease to approximately 6 under (the relatively thin) concretions on copper alloys (Ref 27) and to approximately 4.8 under thick concretions on iron (Ref 26). The environment can also become anaerobic, with SRB growth supported by a plentiful supply of organic material from the concretion organisms (Ref 14, 29).

The lower pH inside the concretion contributes to the local dissolution of calcium carbonate and the precipitation of metal corrosion products. The interior of the concretion can be stained black or red-brown by iron corrosion products, green by copper chloride hydroxides, or deep blue to black with iron or copper sulfides (Ref 26, 27, 29). In shipwrecks where a collection of artifacts becomes encased with a concretion, several different metals can be in contact or can be corroding in close vicinity. This often results in unusual corrosion product formation. The metal can also completely corrode, leaving powdery corrosion products inside a very detailed natural mold of the object.

Corrosion of Metals during Burial

In antiquity, metals such as gold, copper, and meteoric iron were available in their native form, while other metals, such as tin, lead, and silver, were extracted from their ores. Ancient metals and alloys were made into functional or decorative objects by working or casting (Ref 30). The approximate dates for the first widespread use of various metals are listed in Table 2 (Ref 31). The development of copper smelting led to the Bronze Age (~3000 to 1200 B.C.), and improvements in technology led to the Iron Age (~1200 B.C.) and the Industrial Revolution (A.D. ~1750 to 1850) (Ref 32–36).

Metals are, in general, inherently unstable, and when buried, they react with their environment and convert to more thermodynamically stable corrosion products, such as metal oxides. The

reaction products can be solid corrosion products (often with beautiful colors) or dissolved species. Some of the corrosion products identified on archaeological metals are listed in the following tables, along with their mineral name, chemical formula, and the mineral color: Table 3 (copper alloys), Table 4 (silver alloys), Table 5 (iron alloys), Table 6 (lead), and Table 7 (tin and pewter). The outer corrosion layer often incorporates soil minerals; quartz grains, associated burial material; and possibly, organic residues (Ref 37). Depending on the burial environment,

metal artifacts can corrode slowly or quickly. The survival of metal artifacts for long periods of time is aided by the formation of adherent corrosion products that slow the corrosion rate, because the adherent material slows the rate at which oxygen and other environmental species reach the underlying metal. The corrosion rate is also influenced by other environmental factors, such as modern pollutants (e.g., deicing salts, fertilizers, acid precipitation), by associated burial material, or by being located in a burial site with human remains.

Table 3 Some corrosion products identified on archaeological copper alloys

Chemical name	Mineral name	Chemical formula	Color
Oxides and hydroxides			
Copper oxide	Cuprite	Cu ₂ O	Red
Carbonates			
Copper carbonate hydroxide	Malachite	Cu ₂ CO ₃ (OH) ₂	Green
Copper carbonate hydroxide	Azurite	Cu ₃ (CO ₃) ₂ (OH) ₂	Blue
Copper sodium carbonate trihydrate	Chalcanatronite	CuNa ₂ (CO ₃) ₂ · 3H ₂ O	Blue
Chlorides			
Copper chloride	Nantokite	CuCl	Pale gray
Copper chloride dihydrate	Eriochalcite	CuCl ₂ · 2H ₂ O	Blue-green
Copper chloride hydroxide	Atacamite	Cu ₂ Cl(OH) ₃	Green
Copper chloride hydroxide	Clinoatacamite	Cu ₂ Cl(OH) ₃	Green
Copper chloride hydroxide	Paratacamite	Cu ₂ Cl(OH) ₃	Green
Copper chloride hydroxide	Botallackite	Cu ₂ Cl(OH) ₃	Green
Phosphates			
Calcium copper sodium chloride phosphate pentahydrate	Sampleite	CaCu ₅ NaCl(PO ₄) ₄ · 5H ₂ O	Blue-green
Copper hydroxide phosphate	Libethenite	Cu ₂ (OH)(PO ₄)	Green
Sulfides			
Copper sulfide	Chalcocite	Cu ₂ S	Black
Copper iron sulfide	Chalcopyrite	CuFeS ₂	Yellow
Copper sulfide	Geerite	Cu _{1.6} S	Black
Copper sulfide	Digenite	Cu _{1.8} S	Blue-black
Copper sulfide	Djurleite	Cu _{1.96} S	Black
Copper sulfide	Covellite	CuS	Dark blue
Sulfates			
Copper hydroxide sulfate	Brochantite	Cu ₄ (OH) ₆ SO ₄	Green
Copper hydroxide sulfate	Antlerite	Cu ₃ (OH) ₄ SO ₄	Green
Copper hydroxide sulfate monohydrate	Posnjakite	Cu ₄ (OH) ₆ SO ₄ · H ₂ O	Light blue
Copper iron hydroxide sulfate tetrahydrate	Guildite	CuFe(OH)(SO ₄) ₂ · 4H ₂ O	Yellow-brown
Copper chloride hydroxide sulfate trihydrate	Connellite	Cu ₁₉ Cl ₄ (OH) ₃₂ (SO ₄) ₃ · 3H ₂ O	Blue

Table 2 Approximate date of first widespread use of various metals

Metal	Date	Location
Copper		
Native copper	~7000 B.C.	Near East
Smelted copper	~5000 B.C.	Near East
Lead	6000–5000 B.C.	Near East/ Balkans
Gold	5000–4000 B.C.	Balkans
Tin	4000–3000 B.C.	Near East
Silver	4000–3000 B.C.	Balkans/Near East
Nickel		
Copper-nickel alloys	2000–1000 B.C.	Near East
Iron	1000–0 B.C.	Near East
Zinc		
Copper-zinc	A.D. 100–200	Rome
Zinc metal	A.D. 900–1000	India
Aluminum	A.D. 1800–1900	Europe/United States

Table 4 Some corrosion products identified on archaeological silver alloys

Chemical name	Mineral name	Chemical formula	Color
Chloride and bromide			
Silver chloride	Chlorargyrite(a)	AgCl	White
Silver bromide	Bromargyrite	AgBr	Yellow
Silver bromide chloride	Embolite	Ag(Br, Cl)	Yellow
Sulfides			
Silver sulfide	Acanthite	α-Ag ₂ S	Black

Potential-versus-pH (Pourbaix) Diagrams for Specific Metals.

Theoretical potential-versus-pH diagrams (Pourbaix diagrams) can be calculated for metals using thermodynamic data (Ref 17, 22, 38). They provide information about the regions where a metal is corroding and where it can become covered with stable corrosion products. Such calculated diagrams are useful for predicting corrosion behavior. For a given burial site, an accurate Pourbaix diagram can be calculated (using the concentrations of dissolved species in that site) and used as a model to predict the corrosion behavior for metals buried at that site (Ref 39).

Calculated Pourbaix diagrams are useful for interpreting results from measurements of a metal artifact electrode potential (its corrosion potential) and its surface pH, from corrosion product analysis, and from other environmental and electrochemical data. In marine environments, corrosion potential measurements have been used to monitor metals associated with shipwrecks (Ref 40–43). Related studies have been carried out for metal artifacts buried in terrestrial sites (Ref 39, 44, 45).

Patinas. In the context of archaeological metals, particularly copper alloys, the term *patina* is usually associated with the attractive appearance of corrosion products that have formed on metal artifacts after long periods of burial (Ref 37, 46). On high-tin bronzes (i.e., copper alloys containing 20 to 25% Sn), the patinas are often relatively smooth, and they preserve the detail and shape of an artifact, even after thousands of years of burial (Ref 47–49). They can also be highly valued because of their beautiful colors, especially the ones with an overall green color interspersed with splashes of blue (Ref 50). However, the term *patina* is also used in a general sense to describe the surface appearance (attractive or not) of the corrosion products on any archaeological metal artifact (Ref 50).

Copper Alloys. During long periods of burial, the extent of corrosion of copper alloy artifacts ranges from slight (in certain anaerobic sites), with the surface remaining bright, to completely destroyed (in acidic, oxygen-rich deposits), with only a green stain left behind (Ref 12). The extent of corrosion for many other copper alloy artifacts falls in between these two extremes, with some of the metal converted to corrosion products. Copper(I) compounds (cuprite, nantokite, chalcocite) typically form next to the metal surface and, in oxygen-containing environments, green, blue, or blue-green copper(II) compounds form (malachite, atacamite) over the copper(I) compounds. The composition of the copper(II) compounds in the outer layer depends on the relative concentrations of environmental species (Ref 51). Table 3 lists some corrosion products identified on archaeological copper alloys.

Terrestrial Environments. When copper alloys corrode in soil, many of them form a cuprite crust adjacent to the metal and overlaid with green malachite, a copper carbonate

hydroxide (Ref 37). Malachite is a common corrosion product because of the reaction between copper and carbon dioxide gas present in humid air or dissolved in groundwaters percolating through damp soil (Ref 1, 13, 37, 50). The uniform growth of malachite produces the attractive green patina on many bronze antiquities (Ref 37). Azurite, a blue copper carbonate hydroxide, is identified less frequently and is less stable than malachite. Azurite is usually located in discrete patches in association with malachite (Ref 37, 50). Chalconatronite, another blue copper compound, has been identified on ancient Egyptian bronzes recovered from soil rich in various salts as a result of evaporation (Ref 52). Chalconatronite can also form on artifacts after treatment in sodium-base solutions (see the section "Treatment of Bronze Disease" in this article). Copper chloride hydroxides are sometimes identified on archaeological copper recovered from terrestrial sites with a high chloride content, such as sites located close to roads where deicing salts are used in the winter (Ref 1, 13). Eriochalcite, a rare blue-green copper chloride, has been identified on a copper alloy object from Egypt (Ref 53).

Nantokite, a copper(I) chloride, can precipitate under or within the cuprite layer when conditions have become sufficiently reducing and acidic because of the inward diffusion of environmental chloride ions toward the anodic regions on corroding copper (Ref 37, 54, 55). Nantokite is soft, has a grayish appearance like paraffin wax, and can be stained green (Ref 50). The accumulation of nantokite (or soluble chloride ions) within the corrosion layers on archaeological copper alloys can result in a corrosion problem after excavation known as bronze disease (see the section "Copper Alloys (Bronze Disease)" in this article).

On bronzes containing a high tin content (e.g., 20 to 25%), two different kinds of patina can form: One type is even and compact, and the other is uneven and rough (Ref 12). High-tin bronzes with an even, compact patina (sometimes called water patina) are highly valued because of their beautiful lustrous appearance, with colors ranging from blue, green to dark green, dark gray, to black (Ref 12, 37, 47–49, 56). The compact patina is thought to form by the selective (and slow) dissolution of copper and the conversion of tin into cassiterite and other tin oxides (Ref 48, 49, 56). Because there is no significant volume change in the outer corrosion layer, the original shape of the artifact is preserved (Ref 47, 49). The uneven, rough, and crusty patinas that form on high-tin bronzes can be quite thick and often contain a mixture of copper chloride hydroxides and malachite over a cuprite layer (Ref 12, 47). These patinas are thought to form under conditions where there is a high corrosion rate, and the original shape of the artifact is usually damaged because of significant volume changes due to corrosion product formation (Ref 47, 49).

Marine Environments. Concretions on copper alloys are usually relatively thin because of

the toxic nature of copper corrosion products (Ref 27). Atacamite, a copper chloride hydroxide, usually forms on copper alloys exposed to an aerated marine environment (Ref 57). Various green copper(II) chloride hydroxides (mainly atacamite and paratacamite, rarely botallackite) are often identified on copper alloy artifacts recovered from aerobic marine environments (Ref 37, 50, 57, 58). Recent work by Jambor et al. shows that the x-ray diffraction reference pattern Powder Diffraction File 25-1427 had been incorrectly assigned to paratacamite (rhombohedral) and instead corresponds to a monoclinic crystal structure, newly named clinoatacamite (Ref 59). In the past, clinoatacamite may have been misidentified as paratacamite. Nantokite, the copper(I) chloride, is rarely found on marine copper alloys, presumably because the conditions beneath concretions (pH ~6) are rarely acidic and reducing enough for it to precipitate (Ref 14).

Anaerobic Environments. Dark-colored copper sulfides form on copper artifacts when they are exposed to hydrogen sulfide generated by SRB in anaerobic environments (Ref 19, 24, 50, 57, 60). The corrosion layer can be relatively thick and uneven and can obscure the shape and surface details of an artifact (Ref 60), or it can be relatively thin, uniform, adherent, and protective (Ref 24). Some copper alloy artifacts, protected by copper sulfides, have survived hundreds of years on shipwrecks (Ref 14). Copper sulfides (chalcocite, covellite, digenite, djurleite) have been found on copper alloys recovered from reducing marine environments (Ref 57). Copper sulfides (chalcocite, covellite, djurleite, geerite) have also been identified on copper alloy artifacts recovered from waterlogged sites (Ref 24, 60). Chalcopyrite, a dull gold-colored copper iron sulfide, has been found on copper alloy artifacts, where, because it looks like gilding, it is called pseudogilding (Ref 24, 50, 60–63).

Rarer Corrosion Products. There are rare instances where copper hydroxide sulfates (e.g., brochantite, antlerite, posnjakite) have formed on archaeological copper alloys in soil (contaminated by acid precipitation) (Ref 64) or in freshwater sediments (from the oxidation of copper sulfides) (Ref 24). Bright-blue connellite has also been identified on copper alloys recovered from both marine and terrestrial environments (Ref 37, 57, 65).

The phosphate-containing copper corrosion products, green libethenite and blue-green sampleite, have been identified on copper alloy artifacts (Ref 37, 53, 66). The source of phosphate ions in the burial environment is often from bones or from phosphate-rich soils, such as found in Egypt. Studies of archaeological bronzes recovered in Sweden have shown that phosphate ions in soil (as well as high concentrations of soot) accelerate the corrosion of copper alloys during burial (Ref 3, 13).

Smithsonite (zinc carbonate, ZnCO_3) has been identified on copper alloys rich in zinc (Ref 13). Lead compounds, such as cerussite and pyromorphite, have been identified on archae-

ological copper alloys containing lead and recovered from terrestrial environments (Ref 13, 67, 68). The patina in copper-tin bronzes is often enriched with tin oxides (Ref 48, 49, 56, 67). In marine environments, copper alloyed with tin, zinc, or lead can become covered with various tin, zinc, and lead compounds in addition to copper compounds from the corrosion of these alloying elements (Ref 57).

Silver. Archaeological silver artifacts are typically made from silver-copper alloys. Depending on the aggressiveness of the environment, silver artifacts can develop a thin patina, or all the metal can be converted to silver corrosion products (Ref 12). Table 4 lists some corrosion products identified on archaeological silver alloys.

In well-aerated burial environments, either marine or terrestrial, the silver in these alloys reacts with dissolved halide ions to form various silver halide compounds. Chlorargyrite (silver chloride, also known as horn silver or cerargyrite) is often identified on archaeological silver; less frequently identified are bromargyrite and embolite (Ref 12, 57). During burial, silver-copper alloys often become encrusted with green copper(II) compounds (becoming indistinguishable from corroded copper alloys) as copper in the alloy corrodes, is selectively removed from the alloy, and is deposited as green malachite or atacamite on the outer surface (Ref 12).

In anaerobic environments where SRB are active, silver reacts with hydrogen sulfide to form black sulfides, such as acanthite, or, if copper is also present, argentite, jalpaite, and stromeyerite (Ref 14, 57). In its pure state, argentite exists above 175 °C (350 °F), but if its structure also contains some copper, argentite can exist at room temperature (Ref 19).

During long periods of burial, silver artifacts can become extremely brittle (and fragile) because of microstructural changes or corrosion of the alloy (Ref 69). Microstructurally induced embrittlement is attributed to long-term aging at relatively low temperatures, where precipitation of impurities (e.g., lead) weakens the grain boundaries. Corrosion-induced embrittlement is attributed to segregation of copper at grain boundaries and subsequent intergranular corrosion caused by localized galvanic attack.

Gold and Gilded Metals. Pure gold is rarely corroded by burial environments, although certain organic material (humic material) in reducing environments can dissolve gold (Ref 70). Gold alloys and gilded metals are, however, subject to various forms of corrosion that depend on the local burial conditions. For example, ancient Egyptian gold alloy artifacts, such as the gold recovered from Tutankhamen's tomb, can have a distinctive red or purple surface coloration, identified as gold silver sulfides (uytenboogaardtite, petrovskaitite, see Table 4) in a tarnish layer formed in the presence of hydrogen sulfide in the burial environment (Ref 71). During burial in soil or marine environments, the outer surface of gold artifacts can become completely

obscured by corrosion products (e.g., green malachite or atacamite, black silver sulfides, light-sensitive silver chloride) coming from the corrosion of the copper or silver in gold alloys or in alloys beneath the gilding (Ref 12, 72). Corrosion beneath the gilding will cause the gilding to become detached from the underlying metal. Finally, gold-silver and gold-copper alloys are also susceptible to intergranular stress-corrosion cracking during burial, which leaves the artifacts in a brittle and fragile state (Ref 72). Galvanic effects contribute to a greater susceptibility to corrosion for gold alloys with higher silver or copper contents.

Iron. Because iron is a relatively active metal, its corrosion rate in many burial environments is quite rapid compared to other common metals of antiquity. The survival rate of iron artifacts is influenced by the burial environment. In aggressive environments, for example, iron objects can be mineralized into solid lumps of iron corrosion products, with little or no metal remaining (Ref 12). On the other hand, iron artifacts buried in anaerobic conditions can survive in a well-preserved state for thousands of years if SRB activity is suppressed (Ref 18). Table 5 lists some corrosion products identified on archaeological iron alloys. The corrosion products that form on iron corroding under reducing conditions are generally iron(II) compounds, such as siderite, vivianite, and pyrite (Ref 73). Under oxidizing conditions the corrosion products on iron are red-brown iron(III) compounds, typically goethite, an iron hydroxide oxide, or black magnetite, an iron(II, III) oxide (Ref 74). Hematite, a red iron oxide, does not normally form as a corrosion product under burial conditions but is sometimes identified on archaeological iron. Because hematite forms when goethite is heated (above approximately 250 °C, or 480 °F), its presence is usually attributed to an object being exposed to fire before burial (Ref 12).

Terrestrial Environments. When iron corrodes during burial in damp, aerated soil, its surface gradually turns into a bulky mass of rust-colored iron corrosion products cemented with soil particles, dirt, clay, and sand (Ref 12). The corrosion products are generally layered, with lower-iron-oxidation-state compounds forming next to the metal surface, and higher-iron-oxidation-state compounds forming an outer corrosion layer. The most common iron compounds identified in the outer corrosion layers are iron hydroxide oxides, mainly goethite and sometimes lepidocrocite (Ref 12, 74). The buildup of corrosion products can lower the corrosion rate of the iron relative to when it was first buried.

Magnetite is the most common iron oxide identified on archaeological iron and is usually located next to the metal surface (Ref 12, 75). When carbonates or phosphates are present in the soil and the conditions are more reducing than are needed for magnetite to form, then protective layers of siderite (an iron carbonate) or vivianite (an iron phosphate) can form (Ref 12, 76). Siderite has been identified on iron artifacts

recovered from waterlogged sites in Denmark and England (Ref 39, 77). Vivianite has been identified on iron artifacts recovered from waterlogged sites in England (Ref 77). Although pure vivianite is white, its color on iron artifacts is typically dark blue, because some Fe^{2+} ions have been oxidized to Fe^{3+} ; the blue color is from a charge transfer between Fe^{2+} and Fe^{3+} ions on adjacent sites (Ref 78). The source of phosphate ions can be from bones in cemeteries, fish waste, garbage dumps, or (more recently) phosphate fertilizers (Ref 75).

The development of corrosion layers on buried iron promotes pitting and, after extended periods, allows for the separation of anodic and cathodic regions (Ref 21, 76). The anodic half-reaction (metal corrosion) takes place at the interface between the metal and the corrosion products, and the cathodic half-reaction (oxygen reduction) takes place on the outer surface of magnetite, a good electrical conductor. A schematic diagram illustrating this corrosion process is shown in Fig. 2 (Ref 74). At the metal surface, iron(II) ions dissolve, accumulate, and undergo hydrolysis, promoting local acidification. Electrical neutrality is maintained by negative anions diffusing inward from the surrounding burial environment. Chloride ions, in particular, tend to concentrate at the interface because of their high mobility and because they are often the predominant environmental anions (Ref 21, 29). The net result is that, during burial, the cracks, pores, and open spaces within the corrosion layer on archaeological iron become filled with an acidic iron(II) chloride solution (Ref 21, 74). The highly soluble iron(II) chloride remains in solu-

tion rather than precipitating as a solid, which can only happen at $\text{pH} < 2$ (Ref 76). The accumulation of this acidic, chloride-rich solution on archaeological iron can result in a serious corrosion problem after excavation (see the section "Iron (Weeping, Akaganéite Formation)" in this article).

Marine Environments. Iron artifacts become covered by massive concretions in most marine conditions (Ref 14). The outer part of concretions is mainly white (calcium carbonate), and the part closest to the iron is red-brown and contains iron corrosion products, such as iron hydroxide oxides, magnetite, siderite, or iron sulfides (Ref 26). The iron beneath the concretion develops an acidic pH of approximately 4.8 (Ref 26). This acidity promotes the dissolution of iron corrosion products, allowing them to diffuse away from the surface until they encounter a more alkaline pH and precipitate.

The shape of a wrought iron artifact is not retained after it has corroded in seawater, but the shape of a cast iron artifact is. Traditional wrought iron (as opposed to modern mild steel) is fairly pure iron that contains glassy inclusions of iron silicate slag and has a characteristic fibrous structure caused by the elongation of the slag during the forging process. As some of the iron dissolves from corroding wrought iron, the slag inclusions are uncovered, and the surface develops a characteristic fibrous or lamellar structure (Fig. 3). Eventually, all of the iron in the wrought iron artifact dissolves, leaving a void in the concretion—a mold of which can often be used to determine the original shape of the artifact (Ref 14).

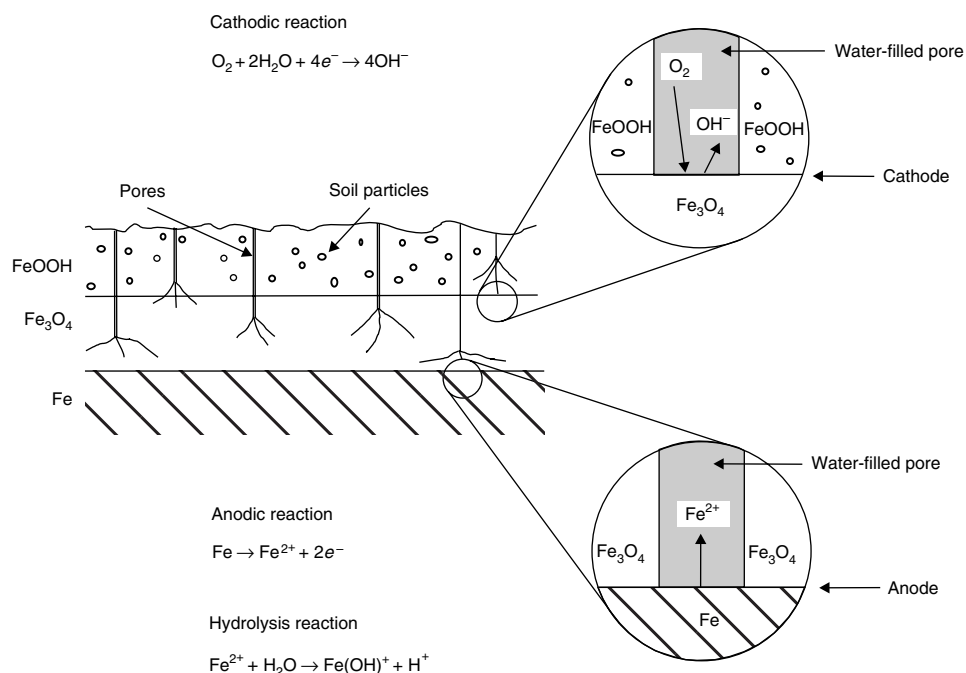

Fig. 2 Schematic diagram showing the corrosion layers on buried iron as well as the separation of anodic and cathodic regions. Adapted from Ref 75

For artifacts made of cast iron (iron alloys containing approximately 2 to 4 wt% C in the form of cementite Fe_3C or graphite), corrosion causes the iron (and eventually the cementite) to dissolve, leaving behind a matrix of soft graphite. This corrosion process is known as graphitic corrosion and is sometimes referred to as graphitization in the conservation literature. The original shape of the artifact (e.g., cast iron cannons and cannon balls) is retained by the graphite matrix, which is usually filled with iron corrosion products (Ref 14).

Anaerobic Environments. Black-colored or gold-colored iron(II) sulfides form on iron artifacts buried in anaerobic environments where SRB are active. The iron sulfides mackinawite, greigite, and pyrite have all been identified on iron artifacts recovered from five different waterlogged land sites in England (Ref 77). Mackinawite initially forms on buried iron because of SRB and then, depending on the oxidizing capacity of the local environment, can transform to greigite, pyrrhotite, or pyrite (Ref 19). Iron sulfides have also been identified in marine concretion (Ref 26) and as precipitates on other archaeological materials: pyrite on waterlogged wood and ceramics, and pyrrhotite on copper alloys (Ref 60, 79). Certain iron sulfides (e.g., pyrite, pyrrhotite) have a metallic luster and yellow-brown color that resemble gold (pyrite is known as “fool’s gold”); iron artifacts (or other material) covered with goldlike iron sulfide layers are said to be pseudogilded (Ref 60, 62, 63).

Lead. In most burial environments, lead artifacts have a relatively slow corrosion rate, because many lead compounds that form in natural burial environments are sparingly soluble or insoluble, and the corrosion products can form an adherent, protective layer on lead. The most common lead corrosion products identified on archaeological lead are carbonates, chlorides, phosphates, and sulfates (Ref 80–82). Table 6 lists some corrosion products identified on archaeological lead.

Lead artifacts exposed to alkaline soil often develop bulky corrosion crusts (Ref 12). In the presence of dissolved carbonate ions, the corro-

sion products are mainly white lead carbonates (cerussite, hydrocerussite) often discolored by oxides, such as red litharge and yellow massicot (Ref 12, 80, 82–84). In acidic soils, lead objects can become very corroded, particularly in the presence of organic acids, because the corrosion products that form are easily soluble in water (especially at $\text{pH} < 5$) and can be leached away (Ref 81, 82). Under certain soil conditions containing chloride ions and a source of phosphate ions (e.g., from decaying bone), pyromorphite can form (Ref 85).

In natural waters, the corrosion of lead depends on the hardness of the water, its pH, and the presence of other dissolved material. When lead artifacts are exposed to hard waters that contain dissolved minerals, such as carbonates, the surface becomes covered with an adherent, protective layer of insoluble salts, usually calcium carbonate along with cerussite and hydrocerussite (Ref 12, 80). In contrast, soft waters do not usually contain enough dissolved material to allow the formation of a protective layer of corrosion products. As a result, the corrosion rate of lead in soft water can be significant—enough to contaminate drinking water (Ref 81). In addition, soft waters that contain organic acids from plants (e.g., peat bogs) promote lead corrosion because of the formation of soluble lead salts. Lead artifacts exposed to such conditions are unlikely to survive for more than half a century (Ref 12, 81).

In marine environments, lead artifacts generally survive extremely well (e.g., several centuries), because they become covered with a protective layer of insoluble lead salts (Ref 12, 82, 86). They may also become covered with a thin layer of concretion (Ref 14). Lead artifacts recovered from an aerobic marine site are normally a light-gray to cream color (Ref 57). The corrosion layer consists of mainly anglesite along with lesser amounts of lead chlorides (e.g., cotunnite, laurionite, phosgenite), hydrocerussite, and the lead monoxides massicot and litharge (Ref 12, 57, 86).

Under anaerobic conditions where SRB are active, lead artifacts become covered with a black layer of galena, because the lead has reacted with hydrogen sulfide (Ref 57, 63). Galena has been found on lead artifacts recovered from anaerobic waterfront sites along the River Thames in London (Ref 60).

Tin and Pewter. Pure tin artifacts are sometimes found at archaeological sites, but it is more common to find tin associated with bronze (a copper-tin alloy), with pewter (either tin-lead alloys or tin-antimony-copper alloys), or as a coating over copper or iron. Leaded tin alloys (e.g., leaded pewter) are relatively resistant to corrosion because they are often protected by lead corrosion products—either lead sulfate (under aerobic conditions) or lead sulfide (under anaerobic conditions) (Ref 14, 57).

In general, when tin corrodes in aerated environments, it forms tin(IV) compounds, typically cassiterite (Ref 57). If oxygen access is

restricted, then tin(II) oxides form, such as romarchite and hydroromarchite (Ref 12, 87). On lead-containing pewters, lead corrosion products can form in addition to tin compounds. Table 7 lists some corrosion products identified on archaeological tin and pewter.

In aerated terrestrial environments, tin alloys corrode, sometimes severely, and become covered with tin oxides, and the color can vary from gray to white (Ref 82, 88). The surface can also be stained green if copper is present in the alloy (Ref 12). Tin artifacts can also undergo intergranular corrosion, making them brittle and fragile (Ref 88). Local corrosion on tin is promoted by anions that form soluble tin salts (e.g., chlorides, sulfates), and the corrosion develops as blisters overlying corrosion pits.

In aerated marine environments, tin alloys tend to be extensively corroded, and their surface becomes covered with mainly cassiterite and rarely schoenfliesite, abhurite, and tin chloride hydroxide (Ref 57, 87). Sometimes, there is no residual metal left, and all that remains is a massive pustular outgrowth of tin corrosion products (Ref 14).

Under anaerobic conditions, tin can be well preserved, as demonstrated by the tin ingots and other tin artifacts recovered from the *Ulu Burun*, a 14th century B.C. shipwreck in Turkey (Ref 89). Well-preserved ingots were covered with a thick, hard, dark-brown patina, presumably tin sulfides, beneath a thick concretion layer (Ref 89). To date, ottemannite (Sn_2S_3) is the only tin sulfide that has been identified on a tin alloy recovered from anaerobic conditions (Ref 57). Other stable tin sulfides exist (e.g., SnS_2 , SnS) and may be identified in the future (Ref 14).

The term *tin pest* is sometimes used to describe the low-temperature phase change that causes tin to expand and disintegrate into a coarse, friable gray powder (Ref 90). The change is from the β phase (white tin, density 7.3 g/cm^3) to the α phase (gray tin, density 5.8 g/cm^3), and it occurs when tin is cooled below 13°C (55°F). The transformation is difficult to initiate, the rate slow, and the change inhibited if small levels of certain impurities (e.g., bismuth, antimony, lead) are present in the tin (Ref 91). Reported cases of tin pest in museum artifacts are generally just normal atmospheric corrosion accelerated by the presence of high relative humidity and pollutants (Ref 90). However, the occurrence of tin pest was recently confirmed on tin ingots recovered from the cold waters surrounding the *Ulu Burun* shipwreck in Turkey (Ref 87, 89).

Aluminum. The use of aluminum only became widespread after 1886 (when an electrolytic process was developed for extracting the metal from its ore), and so the main aluminum artifacts now being recovered from burial environments are aircraft, particularly aluminum aircraft engines. When aluminum corrodes in a burial environment, its surface becomes covered with a gradually thickening layer of aluminum hydroxides ($\text{Al}(\text{OH})_3$) (i.e., bayerite, gibbsite) or aluminum hydroxide oxide ($\text{AlO}(\text{OH})$) (i.e., boehmite) (Ref 92). The surface of aluminum

Fig. 3 A corroded iron chain with the fibrous characteristic of wrought iron. Courtesy of H. Unglik, Parks Canada

becomes pitted if the environment is contaminated by chloride ions. Aluminum alloys, particularly those that contain copper, can suffer more serious corrosion problems (including perforation) because of galvanic corrosion between intermetallic compounds (e.g., CuAl_2) and the aluminum (Ref 14). Because of the relatively few aluminum artifacts recovered from burial environments, little information is available about corrosion products identified on such artifacts. In one instance, aluminum hydroxide (presumably bayerite or gibbsite) was identified on an aluminum engine recovered from a freshwater site (Ref 93).

Corrosion after Excavation

Artifacts may deteriorate rapidly when they are excavated and subjected to a significant change in environment. The form of deterioration depends on the type of metal, its burial environment, and its post-excavation environment (e.g., humidity, temperature, pollutants, handling). Metal artifacts can suffer further deterioration after excavation if they have formed corrosion products that are unstable in damp air, or if they have become contaminated with soluble salts during burial. Salts and other soluble material present in the surface layers of metal artifacts during burial will concentrate and possibly crystallize if the artifact is allowed to dry after excavation. If these salts are hygroscopic, they can promote ongoing corrosion if the surrounding relative humidity is sufficient for them to pick up moisture.

Indoor Environmental Factors. New corrosion problems on excavated metal artifacts can be caused by environmental factors present in a controlled or uncontrolled indoor environment. Exposure of metal artifacts to high relative humidities in an unheated warehouse, for example, will cause most of them to corrode. A well-known example of this is the flash rusting of bare iron; when iron is exposed to damp conditions, it undergoes rapid corrosion and forms bright-orange lepidocrocite. Iron(II) corrosion products identified on archaeological iron appear to be stable if kept dry, but when exposed to damp conditions, they may oxidize. Vivianite may change to strengite, and siderite may convert to iron hydroxide oxides (Ref 39, 76). Although exposure of metal artifacts to light is not usually a problem, color changes have been observed on the light-sensitive silver chloride patina on silver artifacts (Ref 12, 94).

Indoor pollutants can also stimulate new corrosion problems on excavated metals (Ref 95, 96). The key ones are hydrogen sulfide and volatile organic acids, such as acetic (ethanoic) and formic (methanoic) acids (Ref 97, 98). Hydrogen sulfide is released by food, rubber vulcanized with sulfur, protein-based glues, wool, and wooden artifacts excavated from anaerobic burial environments (Ref 99, 100). Hydrogen sulfide can react with silver artifacts to

form black whiskers of silver sulfide and with copper artifacts to form black spots of various copper sulfides (Ref 100, 101). Volatile organic acids are given off by wood (with oak and cedar being the worst), poly(vinyl acetate) adhesives, oil-based paints, and certain sealants and plastics (e.g., cellulose acetate) (Ref 95, 96). Acetic acid and other volatile organic acids can cause copper, iron, lead, and zinc to corrode (Ref 95, 96). Lead is particularly susceptible to corrosion when exposed to acetic acid; lead artifacts become covered with powdery white corrosion consisting mainly of hydrocerussite (Ref 102). For more information on the indoor corrosion of metal artifacts, see the article "Corrosion of Metal Artifacts and Works of Art in Museum and Collection Environments" in this Volume.

Specific Corrosion Problems after Excavation

Corrosion products that formed during burial may no longer be stable in a new postexcavation environment. Contamination, especially by chloride ions, may cause continued corrosion of any remaining metal. Initially, no corrosion problem may be apparent, but over time, new corrosion products can form and damage the artifact. New solids that occupy an increased volume will physically stress the artifact, and new soluble material, especially acid reaction products, can chemically attack the remaining metal. Three important corrosion problems (caused by corrosion processes during burial) that can develop after excavation are weeping and akaganéite formation on iron, bronze disease on copper alloys, and the oxidation of metal sulfides.

Iron (Weeping, Akaganéite Formation). During burial, iron artifacts often become contaminated with an acidic iron(II) chloride solution. If these artifacts are left to dry, then any remaining iron will continue to corrode in a process that can eventually destroy the shape of the artifact (Ref 21, 74, 76). An acid regeneration cycle, proposed by Askey et al. for iron contaminated with hydrochloric acid, can be used to explain why archaeological iron disintegrates during storage if left contaminated with chloride ions (Ref 103):

When an acidic solution of iron(II) chloride is exposed to air, the iron(II) ions in solution can undergo hydrolysis, and oxidation to iron(III) ions and new compounds can form (Ref 74, 76). The crucial factor in this cycle is that the chloride ion forms a soluble salt with iron(II) ions, and it is this solubility that allows the cycle to proceed.

If the iron chloride salt were insoluble, it would precipitate, and the cycle would be broken.

The residual soluble ions support ongoing corrosion that causes chemical damage to any remaining iron metal and physical damage to the shape of the object (Ref 74). The chemical damage is caused by the increased acidity that supports the reaction that consumes the remaining iron. The physical damage is caused by the formation of solid iron hydroxide oxides (e.g., goethite, lepidocrocite, akaganéite) within the corrosion layers; these corrosion products have molar volumes approximately three times greater than the molar volume of iron metal (Ref 104, 105). The formation of any of these iron oxyhydroxides within or below the corrosion layer causes stresses, cracks, and damage, which in turn allow easier access for oxygen and moisture, and continued corrosion. Visual symptoms of continuing corrosion induced by chloride contamination on archaeological iron are the formation of akaganéite and weeping.

Akaganéite Formation. The formation of characteristic bright red-brown elongated particles of akaganéite at exposed metal surfaces on excavated archaeological iron is a symptom of active corrosion (Ref 21, 74, 106, 107). Akaganéite particles form at the metal surface underneath the corrosion products and push them off. Figure 4 contains an image of akaganéite (Ref 74).

Laboratory studies of the formation of iron hydroxide oxides from acidic iron(II) chloride solutions have demonstrated that akaganéite precipitates when the chloride ion concentration is high ($\sim 2\text{ M}$) and that goethite and/or lepidocrocite precipitate when the chloride ion concentration is low (Ref 104). Studies of akaganéite have determined that chlorine atoms are present in the crystal structure (approximately 0.2 wt% Cl), located inside tunnels, and a more representative chemical formula for akaganéite is suggested to be $\text{FeO}_{0.833}(\text{OH})_{1.167}\text{Cl}_{0.167}$ (Ref 108–110). Because akaganéite only forms under conditions of relatively high concentrations of chloride ions, the identification of akaganéite on archaeological iron is an indication

Fig. 4 Scanning electron micrograph of akaganéite on an archaeological iron fragment (gold coated). 600 \times ; picture width, 190 μm . Adapted from Ref 74

that the object is contaminated with high levels of chloride ions (Ref 110).

Weeping. Another symptom of a corrosion problem on excavated iron is the formation of either wet bubbles of acidic liquid (referred to as weeping or sweating iron) or dry, hollow, red spherical shells on an artifact surface (Ref 12, 74, 111). Weeping is attributed to the hygroscopic nature of iron chloride salts (Ref 106). Iron(II) chloride and iron(III) chloride are both hygroscopic and form a series of salts with different waters of hydration, depending on the relative humidity. Iron(II) chloride, for example, deliquesces above a relative humidity of 56% (Ref 112). When the relative humidity is high, these salts absorb water, dissolve, and form wet droplets of orange liquid (Ref 74). Iron hydroxide oxides precipitate around the outside of the droplets (because iron(II) ions in solution undergo oxidation and hydrolysis) and generate a framework for the spherical shells. An example of these hollow shells is shown in Fig. 5 (Ref 74).

Copper Alloys (Bronze Disease). The term *bronze disease* has long been used to describe the appearance of powdery light-green spots on the surface of archaeological copper alloys (Ref 113, 114). Artifacts exhibiting this form of corrosion were once said to be diseased or sick, and the cause was attributed to bacterial or fungal infection (Ref 113). However, it is now known that this corrosion is caused by chloride contamination, either as solid nantokite or soluble chloride ions (Ref 37, 115, 116).

Bronze disease is defined as “the process of interaction of chloride-containing species within the bronze patina with moisture and air” (Ref 116) and also as “a progressive deterioration of ancient copper alloys caused by the existence of cuprous chloride (nantokite) in close proximity to whatever metallic surface may remain” (Ref 37).

The main source of bronze disease on terrestrial archaeological copper alloys is nantokite, usually located adjacent to remaining metal and

beneath the outer layers of stable corrosion products. As long as nantokite is isolated from the surrounding air by outer layers of corrosion, it remains unreacted. However, if the protective outer material covering the nantokite is cracked, damaged, or removed, the nantokite is exposed to the surrounding environment. Once exposed, it can react with moisture in the air to form green copper chloride hydroxides (e.g., atacamite, clinoatacamite, paratacamite)—the symptoms of bronze disease. A schematic diagram of bronze disease is shown in Fig. 6 (Ref 114).

Two proposed reactions for the oxidation and hydrolysis of nantokite are (Ref 116, 117):

The reaction products are green copper chloride hydroxides and soluble ions, either hydrochloric acid or copper(II) chloride (both of which promote further corrosion of the remaining metal).

On archaeological copper alloys recovered from marine environments, nantokite rarely precipitates (Ref 14). The artifacts are instead contaminated with chloride ions that have accumulated during burial. These chloride ions, if not removed, can stimulate copper corrosion and generate green copper chloride hydroxides, the same corrosion products that form in bronze disease on terrestrial copper alloys from the reactions of nantokite (Ref 115).

Metal Sulfides. Metals recovered from anaerobic environments where SRB are active can be covered with various metal sulfides, with pyrite being common (Ref 60, 118). Many metal sulfides are unstable in moist air, and they can be oxidized to metal sulfates (Ref 75, 119). The process may even be pyrophoric (Ref 120). Antlerite and guildite, for example, have been

identified in spots of green corrosion formed on excavated artifacts covered with copper and iron sulfides (Ref 60).

The problems associated with the oxidation of pyrite are described as pyrite disease when observed in geological and palaeontological collections (Ref 118, 121). Pyrite can be oxidized in moist air (above approximately 60% relative humidity), and the initial reaction is thought to be (Ref 119, 121):

The predominant oxidation products are sulfuric acid and various hydrated iron(II) sulfates (e.g., melanterite, rozenite). The iron(II) sulfates can be further oxidized to iron(III) hydroxide sulfates (e.g., butlerite). The volume change associated with the oxidation of the sulfides to sulfates causes mechanical damage to any nearby material. Chemical damage to any underlying material (e.g., iron, wood) is caused by the formation of sulfuric acid, because, besides being acidic, it is also hygroscopic, absorbing moisture at low relative humidity (Ref 122).

Timber and wooden artifacts from ancient shipwrecks can become contaminated by SRB activity. During the 333 years that the 17th century warship *Vasa* (1628) lay at the bottom of Stockholm Harbor, hydrogen sulfide diffused into the timber and transformed into elemental sulfur (Ref 123, 124). The wood in the *Vasa* is now suffering severe damage from sulfuric acid formed by the oxidation of that sulfur (Ref 123, 124). When metals are present in the shipwreck, the wood can become contaminated with metal sulfides. Rozenite, for example, has been identified on wood from Viking ships recovered in Denmark (Ref 125), and melanterite has formed on wood from the *Vasa* (Ref 123). These wooden artifacts can suffer problems after excavation if the humidity is high enough to oxidize the metal sulfides and convert them to sulfates. Butlerite, jarosite, and natrojarosite have formed by this process on wood from the *Batavia* (1629), which sank off the coast of Australia (Ref 79).

Archaeological Conservation

Conservation deals with the preservation of cultural heritage artifacts. Archaeological conservation deals specifically with the preservation of excavated material. The two principal goals of the archaeological conservator are to preserve archaeological material (by stabilizing and protecting it from further damage) and to reveal information about an artifact (shape, material, method of manufacture) and its past (history during use and burial). Many professionals (archaeologists, conservators, scientists, and museum curators) work together to achieve these goals.

Fig. 6 Schematic diagram of bronze disease on archaeological copper alloys. Adapted from Ref 114

Archaeologists study artifacts recovered from archaeological sites to learn about the past, and they are most interested in the original shape of an artifact. Coins, for example, are useful to archaeologists for dating a site. Archaeological conservators use a variety of techniques to remove surface corrosion and uncover the shape of and inscriptions on an artifact. Conservators preserve metal artifacts by storing them at low relative humidity or by treating them to remove corrosion stimulants (Ref 12). This is particularly important for archaeological iron, because if it is contaminated by chloride ions, it can continue to corrode, and, if left unchecked, this corrosion can completely destroy an artifact. Several books on conservation detail the various options available for treating archaeological metal artifacts (Ref 12, 126–131).

Conservation Strategies

In general, archaeological conservators examine freshly excavated metal artifacts and establish a record for each artifact to track relevant information about the artifact, including treatment details and storage recommendations. Such a record can contain some or all of the following information:

- Description of artifact, where and when it was found, identification number
- Line drawings, photographs, x-radiographs

- Examination details
- Condition before treatment
- Results of any analytical work
- Treatment details
- Recommendations for storage and long-term care

Metal artifacts, particularly iron, are x-radiographed after excavation to record their shape and help with identification (Ref 12). X-radiographs are also useful in detailing the extent of corrosion and the amount of remaining metal. Figure 7 contains photographs of a 17th century cross from an archaeological site in Ferryland, Newfoundland. Figure 7(a) shows the cross before cleaning, Fig. 7(b) shows an x-radiograph, and Fig. 7(c) shows the cross after cleaning.

Not all artifacts receive the same degree of conservation treatment, because of considerations relating to the cost of conservation versus the importance of artifacts. One site, for example, may yield thousands of similar wrought iron nails (Ref 4). A high degree of intervention may be carried out on important objects for display, while only minimal work may be done on artifacts intended for storage.

Conservation treatments are developed to suit individual artifacts, with the extent of intervention kept to a minimum and reversible treatments used where possible. Corrosion products are often removed in order to reveal the shape of the object. Conservators avoid the use of high tem-

peratures to treat a metal artifact so as not to destroy its technological history preserved in the metallurgical structure (Ref 132). When developing a conservation treatment for individual artifacts, the archaeological conservator takes into account the following:

- Type of metal and its condition
- Need to preserve evidence in soil or corrosion layers
- Expectations and intentions of the user (e.g., archaeologist, curator, museum)
- Aesthetics
- Consideration of future location of artifact (e.g., storage or display conditions)
- Availability of equipment, materials, and funding

Storage Prior to Treatment. When metal artifacts are first excavated, they are stored temporarily until they can be looked at in a conservation laboratory and a decision made about long-term storage or treatment. In general, artifacts recovered from a dry environment are left dry (and are often stored in a dry or desiccated environment), and those from a damp site are kept either damp or wet and are sometimes refrigerated or frozen (Ref 12, 131, 133).

Iron artifacts are particularly sensitive to rapid corrosion after exposure to air, especially those from marine environments. There are examples of freshly excavated marine cast iron cannon balls and cannons heating up because of rapid exothermic corrosion reactions; sometimes, the

Fig. 7 A 17th century gilded wrought iron cross with brass inlay from an archaeological site in Ferryland, Newfoundland. (a) Before cleaning. (b) X-radiograph. (c) After mechanical cleaning. Courtesy of Lil Hawkins and the Canadian Conservation Institute

surface layers have been observed to literally explode when the cast iron is allowed to dry (Ref 115, 133). Excavated iron artifacts are therefore usually immersed in water temporarily until they can be transferred to a more suitable storage solution prior to conservation treatment. Gilberg studied the storage of cast iron cannon balls in water purged with nitrogen gas and in solutions containing the oxygen scavengers hydrazine or sodium sulfite (Ref 134). The sodium sulfite solution proved the most effective at removing oxygen, but it also contributed to an increased corrosion rate of the iron, because the solution supported the growth of SRB introduced along with the cannon balls. Costain studied alkaline solutions for temporarily storing excavated marine and terrestrial iron and recommended alkaline solutions of either alkaline sulfite (a mixture of sodium hydroxide and sodium sulfite) or sodium hydroxide (Ref 135).

Cathodic protection is now being used to minimize corrosion on iron artifacts awaiting conservation treatment. Sacrificial anode or galvanic cathodic protection is being used to protect marine iron artifacts in seawater (Ref 136, 137). Aluminum anodes, for example, were used on the wrought iron anchor from the *HMS Sirius* (1790), and zinc anodes were used on the cast and wrought iron engine from the *SS Xantho* (1872) (Ref 136). Impressed current cathodic protection is being used (in 2004) to protect the *H.L. Hunley* (1864), a wrought and cast iron submarine that was raised off the coast of Charleston, SC, in 2000 (Ref 138).

Mechanical Cleaning. Conservators often use small hand tools (e.g., scalpels, scrapers, wooden sticks, soft brushes, hammers, chisels) to remove material (e.g., soil, extraneous material, concretions, corrosion products) from archaeological metals (Ref 12, 115). Depending on the nature of this material, they may also need to use power tools (e.g., engraving tools, rotary tools, pneumatic chisels) or air-abrasive units (Ref 139). Such methods provide conservators with a controlled approach to uncovering the shape of an artifact (without adding any additional chemicals) and allow them to search for evidence of plating, inlays, enamels, and other associated materials. They remove material until they reach a level (often a discrete, recognizable boundary) that has preserved the original surface of the artifact, allowing them to determine what the artifact is (Ref 12). The best information, including the shape of the artifact, is often retained in the corrosion layers rather than at the surface of any remaining metal.

Desalination. Archaeological objects recovered from burial environments can be contaminated by salts. The concentration and range of dissolved salts is high in artifacts from marine environments and generally less so for artifacts from terrestrial or freshwater environments. Dissolved salts are located in aqueous solutions filling the porosity of the corrosion products and the cracks, voids, and casting porosity in the remaining metal. If these salts are present in high

enough concentration and the artifact is allowed to dry, then crystals of salt precipitate. If seawater is left to evaporate, the most insoluble salts precipitate first and the most soluble ones last, starting with calcium carbonate, followed by gypsum, sodium chloride, magnesium chloride, magnesium sulfate, sodium bromide, and finally potassium chloride (Ref 11). Salt crystallization can cause damage by exerting pressure on surrounding material; more damage can occur if the salts are subjected to fluctuations in relative humidity and go through cycles of deliquescence and crystallization. For some artifacts, soaking or rinsing in water is sufficient to remove soluble salts (Ref 12, 115). For other artifacts, particularly those made from iron alloys or copper alloys, chemicals other than water or a different conservation treatment is needed to specifically remove chloride ion contamination.

Iron artifacts are seriously affected by chloride ion contamination, and research is ongoing about the best approach to remove the contamination (Ref 21). Removal of significant amounts of chloride ions is rarely achieved by soaking in water (Ref 140). One factor contributing to the difficulty in removal of chlorides in terrestrial iron is that they are trapped beneath a hard corrosion crust, making it difficult for any treatment solution to diffuse in or for the chloride ions to diffuse out (Ref 141). Better success has been achieved with alkaline solutions, where various factors contribute to making it easier for the chloride ions to diffuse out of the artifact into the treatment solution (Ref 142). The two alkaline solutions commonly used to treat archaeological iron are sodium hydroxide (Ref 142) and alkaline sulfite (Ref 143).

Copper alloy artifacts recovered from a marine environment are heavily contaminated with chloride ions, and these are removed by extended washing (Ref 37, 115). When the patina needs to be preserved, then washing is done in water or in a sodium sesquicarbonate solution (Ref 144). When the corrosion can be stripped, washing is done using other chemicals, such as sodium dithionite, a strong reducing agent (Ref 145).

Chemical Treatments. In the past, metal artifacts were routinely stripped using chemicals that dissolved all the corrosion products, removed surface detail and evidence of plating, and left only bare metal (Ref 12). The remaining metal remnants were often pitted and bore little resemblance to the shape of the original object (Ref 37). This practice of chemical stripping has now been widely abandoned in favor of other approaches that uncover the original shape of an artifact, which is often preserved in the corrosion products. Chemical treatments are still used in conservation treatments, sometimes to soften concretions or external corrosion crusts, thus making mechanical removal easier, and other times to help in the removal of chloride contamination (Ref 12, 115).

Coins are often recovered as a hoard (a mass of coins) concreted together by corrosion products.

Copper alloy coins, including ones with a high silver content, can be encased in green copper corrosion products. Various chemicals have been used to separate the mass of coins into individual ones, which are then treated to remove the corrosion and reveal the inscriptions (Ref 146). A solution of alkaline Rochelle salt (sodium hydroxide plus potassium sodium tartrate) has been found to be effective and cause the least damage (Ref 147).

Sequestering agents are sometimes used to dissolve corrosion products. They are used with caution because they can etch the metal and, if not well rinsed after use, can cause corrosion problems. Two common sequestering agents used in conservation are ethylenediaminetetraacetic acid (EDTA) and diethylenetriaminepentaacetic acid (DTPA); these are most often used to treat lead but have also been used on metals such as copper alloys (Ref 12, 37).

Treatment of Bronze Disease. Bronze disease is usually treated by immersing artifacts in 3 wt% benzotriazole (a copper corrosion inhibitor) in ethanol under vacuum (Ref 148). Small outbreaks can also be sealed under a layer of silver chloride by reacting nantokite with an ethanol paste of silver oxide (Ref 149). In the past, bronze disease was treated by removing all corrosion products by stripping with various chemicals, many of which were sodium base (Ref 150). Another approach was to use chemicals that interacted with nantokite (the main source of bronze disease) but left the patina relatively unaffected. Sodium carbonate (Ref 151) and sodium sesquicarbonate (Ref 152) solutions were used to convert nantokite to cuprite, and acetonitrile solutions were used to dissolve nantokite (Ref 145).

A new corrosion problem is now appearing on copper alloy artifacts that were treated in the past with sodium-base solutions. Fresh growths of blue corrosion, identified as chalconatronite, are forming because of reactions involving the copper alloy and residual sodium ions (Ref 153). These local spots of blue corrosion have been mistaken for bronze disease.

Electrolytic Techniques. Various electrolytic techniques are used for cleaning and stabilizing metal artifacts. These techniques are usually applied to artifacts with a substantial metal core.

Electrolytic cleaning is used to remove corrosion products from metal artifacts. An electrochemical cell is set up, with the artifact as cathode, an appropriate metal as anode, and a suitable electrolyte. Using a battery or other power supply, electrolysis is carried out and hydrogen gas is generated at the surface of the artifact by the reduction of water, $2\text{H}_2\text{O} + 2e^- \rightarrow 2\text{OH}^- + \text{H}_2$ (g); these conditions may also cause the corrosion products to be reduced to compounds with a lower oxidation state or to the metallic state (Ref 115). The generation of hydrogen gas at the metal interface is usually effective in mechanically removing the overlying corrosion layers (Ref 12). The disadvantage of this process is that it removes all

associated material from the metal surface, including plating, other surface treatments, and information about the original surface of the artifact. Electrolysis can also be used to remove concretions that completely encase a marine artifact (Ref 139) or to locally treat small areas on an artifact surface.

A modification of this cleaning technique is termed galvanic cleaning or electrochemical cleaning (Ref 12, 126). Here, an electrochemical cell is established using an active metal (e.g., aluminum, zinc) as the anode in contact with an artifact (a more noble metal) and immersing them in a suitable electrolyte. Galvanic cleaning was used, for example, to reveal the details of a 7th century A.D. bronze bowl; chalcopyrite (considered dangerous because it may oxidize and form sulfuric acid) was removed by applying a sodium hydroxide solution to a small area and covering it with aluminum foil for short times (Ref 61).

Electrolytic reduction techniques are also used in the removal of chloride ions from contaminated artifacts (Ref 115). Cast iron cannons are often treated using electrolytic reduction (Ref 154). When corroded iron is subjected to electrolysis, the iron hydroxide oxides are thought to be reduced to magnetite, which increases the porosity of the corrosion products and increases the rate at which chloride ions diffuse out of the artifact into the treatment solution (Ref 115, 142, 155, 156). When the removal of corrosion is not wanted, such as in cast iron where the shape of the artifact is maintained by graphite, more controlled reduction techniques (e.g., cathodic reduction at constant potential) are used to avoid the generation of hydrogen gas (Ref 157). Many of the copper alloy artifacts recovered from the *RMS Titanic* (1912) were desalinated using cathodic reduction techniques that avoided the generation of hydrogen bubbles (Ref 158). Recently, cathodic reduction techniques have been used to treat aluminum recovered from marine environments (Ref 93, 159, 160).

Another use of electrolytic reduction techniques is to preserve corroded material by reducing corrosion products back to a cohesive metallic state rather than nonadherent material that is easily brushed away. The reduction process is carried out in a controlled manner that avoids generating hydrogen bubbles and consolidates the corrosion products into a coherent but porous metallic network (Ref 161). There is growing use of cathodic reduction at constant potential for preserving surface details in corroded lead artifacts (Ref 162, 163). A few mineralized archaeological silver artifacts have also been reduced to metallic silver using electrolytic reduction (Ref 164).

Repairs and Reconstruction. Conservators do not try to make the artifact look as it did when new, but they do carry out various repairs or reconstructions to make an artifact more understandable to the viewer and safer to handle. A conservator may reconstruct an artifact by reassembling broken pieces into the shape and

form of the original artifact and then filling in missing areas. Filled areas are painted to match the surrounding surface corrosion (e.g., with powdered iron oxide pigments to match iron corrosion). Repair materials or coatings are chosen so they can be removed at a later date, if necessary. Common adhesives are ones containing acrylics (Ref 12). Metal artifacts are sometimes coated with a wax or lacquer after treatment. The popular lacquers are based on stable acrylic resins, such as Acryloid (Paraloid) B-72 or Acryloid B-48 (Rohm and Haas Co.), or Inralac (Albi Manufacturing Division of Stanchem Inc.), which contains Acryloid B-44 and benzotriazole (Ref 12). Acryloid B-48 is noted for its adhesion to metal.

Long-Term Storage and Display. Metal artifacts that are considered stable (because they have successfully undergone treatment or are considered relatively inert) are usually stored or displayed along with the general collection inside museums, where the relative humidity is controlled to stay below 60% (Ref 96). Metal artifacts that are considered unstable or are showing signs of instability are usually stored under controlled low relative humidity. Bronze disease on copper alloys can usually be prevented by keeping them at relative humidity below 46% (Ref 116). Active corrosion on archaeological iron contaminated with chlorides is thought to be stopped when artifacts are kept at a relative humidity below 20%, although some artifacts may still continue to corrode (Ref 106, 165). Now being tested for storage of archaeological artifacts are commercially available scavengers that create an environment inside a transparent enclosure (e.g., a heat-sealable barrier film) that is extremely dry and oxygen-free (Ref 166).

In Situ Preservation. Consideration is now being given to in situ preservation of artifacts because of the high cost of conservation, the growing number of archaeological sites, and the need for proper artifact storage after conservation (Ref 167, 168). For a site to be suitable for in situ preservation, it must be safe to keep artifacts in that burial environment and leave them for future generations to excavate. Monitoring of environmental parameters, as is being done at the Nydam Mose site in Denmark (Ref 167, 169), will be necessary to ensure that a burial environment remains safe or to detect changes in the local environment that put metal artifacts at risk of accelerated deterioration (Ref 3, 13).

Chemical Cleaning and Cleaning-Related Corrosion of Process Equipment

Revised by Bert Moniz, DuPont Company and Jack W. Horvath, HydroChem Industrial Services, Inc.

CHEMICAL CLEANING is the use of chemicals to dissolve or loosen deposits from process equipment and piping. It offers several advantages over mechanical cleaning, including more uniform removal, no need to dismantle equipment, generally lower overall cost, and longer intervals between cleanings. In some cases, chemical cleaning is the only practical method. Chemical cleaning is usually performed by contractors who specialize in this work. Some cleaning procedures are protected by patents.

The primary disadvantages of chemical cleaning are the possibility of excessive equipment corrosion and the expense of waste disposal. Chemical cleaning solvents must be evaluated in a corrosion test program before acceptance for use.

Chemical Cleaning Methods

There are six major chemical cleaning methods: circulation, fill and soak, cascade, foam, vapor-phase organic, and steam-injected cleaning. A seventh variation is discussed in the section "On-Line Mechanical Cleaning" in this article.

Circulation, the most common method, is applied to columns, heat exchangers, cooling water jackets, and so forth, where the total volume required filling the equipment is not excessive. The equipment is arranged such that it can be completely filled with the cleaning solution and circulated by a pump to maintain flow through the system. Movement of solution through the equipment greatly assists the cleaning action. During circulation, temperature and chemical concentration are measured to monitor the progress. The cleaner may be replenished (sweetened) occasionally to maintain efficiency. Corrosion coupons or on-line monitoring are sometimes used to evaluate the effect of the cleaning chemicals on the equipment materials.

With circulation cleaning, the rate of flow through the equipment is critical. Large-diameter connections are preferred, and a high-capacity pump may be necessary to produce the required circulation flow rate. After cleaning, the

equipment is drained, neutralized, flushed, and passivated. When strong acids are used, circulation flow rates may be limited to reduce corrosion.

Fill-and-soak cleaning involves filling the equipment with the cleaner and draining it after a set period of time. This may be repeated several times. The equipment is then water flushed to remove loose insolubles and residual chemicals.

Fill-and-soak cleaning offers limited circulation. The poor access of fresh cleaning solution to the metal, together with the inability to maintain solution temperature, may cause the cleaning action to cease.

The method is limited to relatively small equipment containing light amounts of highly soluble fouling and to equipment in which circulation cannot be properly controlled. Because good agitation is achieved during the flushing stage, flushing should be as thorough as possible. Circulation and fill-and-soak cleaning are sometimes used alternately.

Cascade cleaning, a modification of the circulation method, is usually applied to columns with trays. The column is partially filled, and the liquid is continuously drawn from the reservoir and pumped to the highest point. The liquid then cascades down through the column, cleaning surfaces as it passes over them. The liquid draw-off point must be suitably located to avoid recirculation of loosed foulants, or filtration must be included in the circulation loop. High-capacity pumps and large-diameter piping are required to achieve the necessary transfer of liquid to produce a flow pattern that will contact all fouled surfaces within the column.

The cascade method is primarily used in large columns and is suitable for most types, except for packed columns. Cleaning is not effective in inaccessible areas, such as the underside of trays, due to poor contact with the cleaning solution. Contact may be improved by injecting air or nitrogen at the base of the column. Air should not be used if iron is dissolved in the solvent to avoid causing ferric corrosion (discussed in the section "Ferric Ion Corrosion" in this article). If steam is

used to heat the chemicals, the location of the steam-injection point should not lead to localized overheating. Ideally, steam heating of the solvent should occur by steam injection in temporary circulation piping or by use of a temporary heat exchanger. High temperature can also increase corrosion in the vapor space.

Foam cleaning uses a static foam generator that employs air or nitrogen to produce a foamed solvent. As with cascade cleaning, air should not be used if iron is dissolved in the solvent. Foam stabilizers may be added to prolong foam life and increase the effectiveness of the cleaning chemicals. Foam cleaning is used on equipment that cannot support full or partial filling with liquid. Foamed solvent will completely fill fouled equipment, contacting all surfaces. Foam cleaning results in significantly less liquid volume for disposal compared with other methods (Ref 1, 2).

Vapor-phase organic cleaning is used in equipment that is difficult to clean with liquids. For example, vaporized organic solvents are used to remove organic deposits from columns. The organic solvent is vaporized, injected into the top of the column, condensed, collected in a circulation tank, and revaporized.

The principal concerns are the handling and disposal of the solvent and its flammability (when applicable). The circulation tank should be purged and blanketed with nitrogen, fitted with an adequate venting and condensing system, and grounded to prevent accumulation of an electrical charge.

Steam-injected cleaning involves the injection of a concentrated mixture of cleaning chemicals into a stream of fast-moving saturated steam. The steam is injected at one end of the system and condensed at the other. The steam atomizes the chemicals, increasing their effectiveness, and ensures good contact with the metal surface.

Steam-injected cleaning is very effective for critical piping systems. It is also injected into the bottom of columns or other vessels in degassing for later personnel entry. As with foam cleaning, the method produces a relatively low amount of liquid for disposal. Steam-injected cleaning

times are much shorter than times required for other methods.

Chemical Cleaning Solutions

A wide variety of standard chemical cleaning solutions are available (Table 1). Many proprietary solutions are based on these chemicals. Some are patented or involve patented equipment. Chemical cleaning contractors are the best source of information on standard or patented techniques.

For decades, common practice among industrial cleaning contractors and their customers has been to use volume percent (vol%) for surfactants and corrosion inhibitors. Other cleaning chemicals are used on a weight percent (wt%) basis. For acids, the weight percent refers to the concentration of the pure active acid compound in the solution. In this article, concentration is given as weight percent, unless stated otherwise.

For chelants, a sometimes confusing practice used by some contractors is to refer to chelant concentrations as weight percent of the concentrated chelant solution sold by the manufacturer. Ethylenediaminetetraacetic acid (EDTA) salts are commonly sold as approximately 40% active EDTA concentrates. So 15 wt% chelant, by that practice, means $15 \times 0.40 = 6$ wt% as active EDTA. Since other contractors may describe the same concentration solution as 6 wt%, the reader should inquire as to exactly what the active EDTA solids content is

for clarity and to be able to compare proposals on a realistic basis.

Chemical cleaning solutions include mineral acids, organic acids, bases, complexing agents, oxidizing agents, reducing agents, and organic solvents. Inhibitors and surfactants are added to reduce corrosion and to improve cleaning efficiency. Following the cleaning cycle, a passivating agent can be introduced to retard further corrosion or to remove trace ion contamination.

Mineral acids are strong scale dissolvers. They include hydrochloric acid (HCl), hydrochloric acid/ammonium bifluoride (HCl/NH₄HF₂), hydrofluoric acid (HF), sulfuric acid (H₂SO₄), nitric acid (HNO₃), phosphoric acid (H₃PO₄), and sulfamic acid (NH₂SO₃H).

Organic acids are much weaker scale dissolvers. They are often used in combination with other chemicals to complex scales. An advantage of organic acids is that they may be disposed of by incineration. They include formic acid (HCOOH), hydroxyacetic/formic acid (HOCH₂COOH/HCOOH), acetic acid (CH₃COOH), and citric acid (HOOCCH₂C(OH)(COOH)CH₂COOH).

Bases are principally used to remove grease or organic deposits. They include alkaline boilout solutions and emulsions.

Complexing agents are chemicals that combine with metallic ions to form complex ions, which are ions having two or more radicals capable of independent existence. Ferricyanide [Fe(CN₆)]⁴⁻ is an example of a complex ion.

Complexing agents are of two types: chelants and sequestrants. Chelants complex the metallic ion into a ring structure that is water soluble and resistant to precipitation. Sequestrants complex the metallic ion into a structure that is water soluble and resistant to precipitation, but has no ring structure.

Oxidizing agents are used to oxidize compounds present in deposits to make them suitable for dissolution. They include chromic acid (H₂CrO₄), potassium permanganate (KMnO₄), and sodium nitrite (NaNO₂).

Reducing agents are used to reduce compounds in deposits to a form that makes them suitable for dissolution and to prevent the formation of hazardous by-products. They include sodium hydrosulfite (NaHSO₂) and oxalic acid (HOOC⁻COOH). Reducing agents are also used to prevent ferric iron corrosion. (See the discussion on ferric corrosion found later in this article.)

Inhibitors are specific compounds that are added to cleaning chemicals to diminish their corrosive effect on metals. Most inhibitors are complex proprietary mixtures, and recommendations for their use are available from the supplier.

Surfactants are added to chemical cleaning solutions to improve their wetting characteristics. They are also used to improve the performance of inhibitors, emulsify oils, and for the foaming of solvents. Surfactants are primary ingredients in detergents that are used in neutral, acidic, and alkaline solutions. As with inhibitors, surfactants are trade name products, although

Table 1 Deposit types, solvents, and incompatibilities

Deposits	Commonly used solvents(a)	Temperature		Construction material incompatibilities(b)
		°C	°F	
Iron oxide: mill scale, or magnetite, Fe ₃ O ₄ ; red iron oxide, or rust, Fe ₂ O ₃	5–15% HCl 2% hydroxyacetic/1% formic Ammonium bifluoride (ABF additive), NH ₄ F·HF	50–80 88–96 Depends on acid choice	120–175 190–205	Stainless steels, Incoloy 800, soft metals Soft metals Titanium, zirconium, stainless steels, Incoloy 800, soft metals
Copper oxide, CuO copper metal, Cu	Chelants: EDTA salts, citric acid salts HCl + thiourea additive Buffered aqua ammonia + oxidizer; ammoniated citric or EDTA salts + oxidizer	65–150 50–65 50–65	150–300 120–150 120–150	Soft metals Copper alloys, stainless steels, Incoloy 800, soft metals Copper alloys, soft metals
Water scale, mainly calcium carbonate, CaCO ₃	5–15% HCl 7–20% sulfamic acid 5–10% formic acid Chelants: EDTA salts	50–65 50–65 50–82 65–150	120–150 120–150 120–180 150–300	Stainless steels, Incoloy 800, soft metals Soft metals
Phosphates, or hydroxyapatite, Ca ₁₀ (OH) ₂ (PO ₄) ₆	5–15% HCl Sodium EDTA 7–20% sulfamic acid	65–80 65–150 50–65	150–175 150–300 120–150	Stainless steels, Incoloy 800, soft metals Soft metals
Calcium sulfate, CaSO ₄	Potassium hydroxyacetate or potassium acetate, followed by acid stage 5–15% HCl	20–82 80–88	70–180 175–190	Depends on the choice of acid Stainless steels, Incoloy 800, soft metals
Silica, SiO ₂ , or silicate compounds	Long alkaline boilout: followed with acid stage: HCl + NH ₄ F ₂ (ABF)	50–65	120–150	Titanium, zirconium, stainless steels, Incoloy 800, soft metals
Common black iron sulfides, FeS	3–7.5% HCl + H ₂ S suppressor or use scrubber 5–15% sulfuric acid, H ₂ SO ₄ + H ₂ S suppressor or scrubber	50–65 50–65	120–150 120–150	Stainless steels, Incoloy 800, soft metals Martensitic stainless steels, soft metals
Disulfides, FeS ₂	Chromic acid followed by an acid stage Alkaline permanganate (AP), followed by an acid stage	Boiling >82	Boiling >180	Depends on the choice of acid Depends on the choice of acid
Carbonaceous deposits, organolignins, other hard organic residues	3% sodium hydroxide + 2% potassium permanganate solution (AP) for thin deposits, followed by acid	82–95	180–205	Soft metals. (Oxalic acid in the rinse between stages prevents chlorine gas generation from HCl + MnO ₂ .)
Heavy hydrocarbons: tars and asphalts	Alkaline detergents, emulsion solvents	50–95	120–205	Soft metals (if strong alkali is used). (Stay below flash points of solvents.)
Light hydrocarbon: fuels, oils, and greases	Detergents, with or without alkali additives, depending on the deposits	20–82	70–180	Soft metals (if strong alkali is used)

(a) All acids and chelants should be used with corrosion inhibitor additives. (b) Soft metals are low strength metals with low corrosion resistance, such as zinc (galvanizing), aluminum, and magnesium.

some are so common as to approach commodity status.

Hydrochloric acid is the least expensive and most widely used solvent for water-side deposits on steels. The concentration and temperature vary from 5 to 15% and 50 to 80 °C (120 to 175 °F). The acid is generally replenished if the concentration falls below 4%.

Hydrochloric acid must always be used with a filming inhibitor to minimize corrosion. Inhibited HCl is usually suitable for cleaning carbon or alloy steel, cast iron, brasses, bronzes, copper-nickel alloys, and UNS N04400 (Monel 400).

Hydrochloric acid, even inhibited, is not recommended for cleaning stainless steels, UNS N08800 (Incoloy 800), UNS N06600 (Inconel 600), aluminum, or galvanized steel. Its applicability for cleaning titanium or zirconium depends on the contaminants present in the acid. Some technical-grade hydrochloric acid streams are contaminated with HF.

Hydrochloric Acid/Ammonium Bifluoride (ABF). The addition of about 1% ABF (NH_4HF_2) to hydrochloric acid releases hydrofluoric acid (HF) in the solution. This not only acts as an accelerator for the solvent, but more importantly also aids in dissolving silicate scales. A filming inhibitor should be added. Materials compatibility is similar to that of hydrochloric acid except that titanium, zirconium, or tantalum should never be exposed to an acid containing ABF or hydrofluoric acid because they will dissolve rapidly. For calcium water scales, the concentration of ABF additive should be limited to 0.75% or less to prevent the precipitation of calcium fluoride (CaF_2).

Hydrofluoric acid can be used as a pre-operational cleaner to remove mill scale, at 1 to 2% and 80 °C (175 °F). It is not widely used in North America, primarily because of safety concerns.

Sulfuric acid is used on a limited scale, from 5 to 10% at temperatures up to 82 °C (180 °F). Although inexpensive, it has several disadvantages, including the extreme care required during handling and the precipitation of calcium sulfate (CaSO_4) with deposits containing calcium salts. When inhibited, H_2SO_4 may be used on carbon steel, austenitic stainless steels, copper-nickel alloys, admiralty brass, aluminum bronze, and Monel 400. Sulfuric acid should not be used on aluminum or galvanized steel, and it may be too corrosive on some 400 series stainless steels.

Nitric acid is primarily used for cleaning stainless steel, titanium, or zirconium. It is an extremely strong oxidizer, and its general use is limited because of both corrosion and safety concerns. Conventional inhibitors, detergents, and other additives are not stable in HNO_3 . It should not be used on carbon steel, copper alloys, Monel 400, and most other metals. Piping for handling HNO_3 should be austenitic stainless steel or polytetrafluoroethylene (PTFE) lined. A special corrosion inhibitor for nitric acid has been developed. It has been used successfully on

several chemical cleaning projects in North America.

Phosphoric acid is sometimes used at 2% and 50 °C (120 °F) for 4 to 6 h to pickle and passivate steel piping. It is not as effective as HCl in removing iron oxide scale, but phosphoric acid has proven effective for cleaning stainless steels.

Phosphoric acid was originally used for removing mill scale from new boilers because it also helped passivate the surface. Another use for it is to brighten aluminum. General use of phosphoric acid is limited by its cost, and by the poor solubility of calcium phosphate at low pH values.

Sulfamic acid is used from 7 to 20% at up to 65 °C (150 °F) to remove calcium and other carbonate scales and also iron oxides. It is not as effective as HCl on iron oxides. If sulfamic acid is heated above 75 to 82 °C (170 to 180 °F), it begins to hydrolyze to sulfuric acid, greatly reducing its effectiveness on calcium deposits, and increasing its corrosiveness on metals. ABF is commonly added to sulfamic acid at 0.25 to 1.0% as an accelerator for iron scale dissolution. Although relatively expensive, sulfamic acid is reasonably safe to handle and may be transported as a solid and diluted on-site. This greatly facilitates handling and makes it preferred for in-house cleaning.

Inhibited sulfamic acid can be used to clean carbon steel, copper, admiralty brass, cast iron, and Monel 400. Without the ABF addition, it is effective on most stainless steels.

Formic acid is generally used as a mixture with other acids (such as citric acid) because alone it is a poor solvent for iron oxide deposits. Accelerators such as erythorbic acid or ABF are commonly added to formic acid solutions to improve iron scale dissolution. Formic acid can be used on stainless steels, is relatively inexpensive, and can be disposed of by incineration.

Hydroxyacetic-formic acid (HAF) is used as a 2%hydroxyacetic-1%formic mixture at 80 to 96 °C (180 to 205 °F) to remove iron oxide and calcium deposits. When added, ABF will also remove silica-containing deposits. The acid must be inhibited for use on carbon steel.

HAF is especially advantageous in nondrainable sections of reactors or boilers, because it may be decomposed to harmless by-products by heating to 150 to 175 °C (300 to 350 °F). The primary use of this cleaner is to remove magnetite (Fe_3O_4) in supercritical boilers and in superheater sections of other boilers. It can be used on stainless steels and is applicable in mixed-metal systems.

Acetic acid is used to clean calcium carbonate scales, but it is ineffective in removing iron oxide deposits. The use of acetic acid in chemical cleaning is limited due to its being weaker than formic acid, necessitating extremely long contact times, and also due to higher cost compared to formic acid.

Citric acid at 3% and 65 °C (150 °F) is used to clean iron oxide deposits from aluminum or titanium. Monoammoniated citric acid is

effective in removing iron oxide deposits at pH 3.5. By adjusting the pH to 9 and adding an oxidant, such as sodium nitrite (NaNO_2), copper can be removed with the same solution. A patent on this technique has expired.

Where ammonia is a disposal issue, mono-sodium citrate (MSC) is used in a patented iron scale removal procedure that parallels the monoammonium citrate process, including the passivation. MSC is not effective in copper removal, and great care must be taken to avoid iron salts precipitation.

Citric acid is also used in dilute solution to scavenge residual iron oxide from boilers after HCl cleaning in order to facilitate passivation treatment.

Alkaline boilout solutions are used to emulsify and disperse various oils, greases, and organic contaminants from new steel or stainless steel equipment, such as drum boilers and re-tubed heat exchangers. Examples are combinations of sodium hydroxide (NaOH , or caustic), trisodium phosphate (Na_3PO_4 , or TSP), sodium carbonate (Na_2CO_3 , or soda ash), and sodium metasilicate (Na_2SiO_3). These are added in concentrations of 0.5 to 1% and boiled or circulated hot for many hours, often under pressure. A low-sudsing surfactant is usually added. Proprietary compositions are available from suppliers.

Some operators avoid using NaOH because of the possibility of stress-corrosion cracking (SCC, caustic embrittlement) of steel. A controlled amount of sodium nitrate (NaNO_3) may be added to the NaOH to inhibit cracking.

Alkaline detergents are used to remove coatings of oily material from inorganic deposits. Oily coatings can prevent dissolution of mineral scales by acids or chelants. For light-bodied oil, a TSP + surfactant combination may be circulated for a few hours at 82 to 95 °C (180 to 200 °F) to remove it. The equipment is then flushed with water.

Chelants will complex such deposit metals as iron or copper. Commonly used chelants include EDTA, citric acid, gluconic acid, and nitrilotriacetic acid (NTA).
